Cost of spraying, jarring, etc	300,000
Total	$4,088,814

PLUM, PRUNE, ETC.

There are likewise no figures on the yield of the plum, prune, etc., and the yields of these fruits were determined in a similar manner.

Number of trees in infested territory	15,906,398
Assuming that one-fourth bear every year 1 crate per tree, at 50 cents value	$1,988,299
Estimated annual loss of 50 per cent	$994,149
Cost of treatment, spraying, jarring, etc	250,000
Total	$1,244,149

TOTALS.

Apple	$3,257,806
Peach	3,788,814
Plum, prune, etc	994,149
Total	$8,040,769
Cost of treatments	550,000
Grand total	$8,590,769

LOSSES FROM MISCELLANEOUS FRUIT-TREE INSECTS.

In addition to the more notable insect pests previously indicated, there is a large number of species which in the aggregate cause a very great injury to fruit or tree. Thus, for miscellaneous apple insects, a conservative estimate indicates that about $10,000,000 are lost annually from the attack of such species as canker worms, apple-tree borers, woolly aphis, etc. The pear crop suffers from pear thrips, pear psylla, codling moth, etc., aggregating in all a loss per year of about $1,350,000.

The loss to stone fruits from miscellaneous insect pests is found to be somewhat more than $3,650,000.

Cranberry culture is a relatively small and specialized industry; nevertheless, the losses from insect attack in proportion to the value of the crop is high, amounting to perhaps not less than 25 per cent. Using as a basis the figures furinshed by the American Agriculturist as to yield, the loss from insect attack to the fruit and vine amounts to about $400,000 annually.

The losses to the several crops mentioned from these miscellaneous insects thus total about $15,400,000.

The details for these several calculations are given below.

LOSSES FROM MISCELLANEOUS INSECTS NOT CONSIDERED IN OTHER CALCULATIONS.

Figures of 1900 census taken as a basis except in the case of cranberry insects. Here the figures of yield of fruit as given by the American Agriculturist were used.

Miscellaneous apple insects.

Number of apple trees	201,798,642
Valuation, $1 per tree	$201,798,642
Assuming a total annual injury of 5 per cent each year from such insects as canker worms, woolly apple aphis, green aphis, apple-tree borers, caterpillars, oyster shell and scurfy scales	$10,089,932

Miscellaneous pear insects.

Number of pear trees	17,716,184
Valuation, 75 cents per tree	$13,286,138
Assuming a total annual injury of 10 per cent from such species as pear thrips, pear psylla, pear slug, codling moth, curculio, etc	$1,328,613

Cranberry insects.

The average annual yield of cranberries during the past 4 years was (bushels)	1,057,750
Valuation, $1.50 per bushel	$1,586,625
Assuming a total of 25 per cent loss annually from such species as the yellow and black-head cranberry worms, the fruit worm, etc.	$396,656

Loss from miscellaneous insects to all stone fruits.

Total number of trees (peach, plum, prune, cherry, etc.)	147,753,746
Valuation, 50 cents per tree	$73,876,873
Estimated total loss of 5 per cent to value of trees annually	$3,693,843

DECIDUOUS FRUIT INSECTS.

Summary of total losses, including cost of treatment.

Codling moth	$16,716,667
San Jose scale	10,528,265
Peach-tree borers	6,000,000
Grape insects	8,769,905
Plum curculio	8,590,769
Miscellaneous apple insects	10,089,932
Miscellaneous pear insects	1,328,613
Cranberry insects	396,656
Miscellaneous stone fruits	3,693,843
	$66,114,650

RELATIONS OF BIRDS AND MAMMALS TO THE NATIONAL RESOURCES.

By Dr. C. Hart Merriam,
Chief of Biological Survey, U. S. Department of Agriculture.

INTRODUCTION.

In taking stock of our national resources and considering ways and means for their conservation, it should not be overlooked that an important part of the national assets consist of our insectivorous and game birds, our splendid game animals, and our native fur bearers.

VALUE OF BIRDS ON THE FARM.

Birds at all times and in all places are of direct interest to man. Some prey upon the products of man's husbandry, but by far the greater number prey continuously upon insects and rodents—the ever present enemies of agriculture and forestry. While it is impossible to represent by figures the value of our insectivorous and predatory birds, or to present in the form of statistical tables the number of millions saved annually by their labors, it would be a shortsighted policy indeed that would sanction depletion of their ranks. It is safe to say that upon their presence and well-being depend the existence of our forests and the possibility of successful agriculture. In most States an enlightened policy with regard to insectivorous birds already prevails;.and there is a growing sentiment also in favor of adequately protecting game birds, not only for their food value and as objects of pursuit by sportsmen, but for their demonstrated value as destroyers of insects, in which capacity some of them take first rank. The recognition of their importance in the latter rôle is comparatively recent, and much remains to be done before the public is educated to an understanding of the nature and full extent of their services, and the losses that will inevitably follow serious diminution of their numbers.

A striking illustration of the value of certain of our native birds and mammals in an emergency was afforded during the invasion by field mice of the alfalfa districts of Nevada in 1907, when mice in the Humboldt Valley increased till in places they reached the astonishing total of 12,000 to the acre, and completely destroyed the alfalfa fields. Several species of hawks and owls, many ravens, gulls, and herons, and numerous foxes, skunks, and coyotes speedily assembled and took up permanent residence in the infected district, where they fed almost wholly on the field mice. Though inadequate by themselves to suppress the plague, they contributed important aid, and had not their numbers been previously reduced by years of persistent persecution, it is almost certain that no plague would have occurred, as they would have prevented the increase of the mice. Furthermore, after the mice had been greatly reduced in numbers by systematic and persistent poisoning (in February, March, and April), they continued to decrease under the continuous attacks of their natural enemies until by August they were actually scarce—indicating the efficiency and value of the service rendered by predatory birds and mammals.

VALUE OF INSECTIVOROUS AND THE SMALLER PREDATORY MAMMALS.

The value of our insectivorous mammals, and of those whose food consists largely of destructive rodents, is less generally understood, and the labor of protecting and preserving them for the benefit of future generations of farmers is rendered correspondingly difficult. The lesson that every badger in Wyoming, Colorado, Texas, and other western States has a distinct money value to the public, and that the wanton slaughter of one is a crime against good citizenship, is as yet unlearned by the majority of the population. Foxes, skunks, weasels, and in certain regions even coyotes, have their appointed places on the force of nature's policemen, and a knowledge of the part they play and of the nature and extent of the good they do, as well as of the harm, should be universal.

VALUE OF GAME ANIMALS.

Elk and deer, once so numerous and widespread in the United States, have become so diminished in numbers that to the bulk of our citizens venison has become only a tradition. But by the establishment of game preserves, national parks, and national forests, and by the enactment of wise legislation the scale has been already turned, and the perpetuation of these, the most valuable of our large game animals, seems assured. If, however, they are to retain their place among the national resources and are to become a source of pecuniary profit, something more is necessary than to provide for their continued existence. Since they are among the easiest of animals to domesticate, it is believed, and indeed it has been already demonstrated, that they can be reared in small inclosures and on tracts of brushy land not fit for cultivation. Thus extensive tracts of waste land may be put to profitable use, and at the same time our decreasing meat supply may be materially augmented and its price lowered so as to bring fresh meat within the reach of a considerable part of the population now unable to procure it. One deer breeder states that 20 deer may be kept at the cost of keep of a single Jersey cow.

Value of wild game.—The number of wild deer killed annually in the United States is not known, but the annual kill in six of the Northeastern States (Maine, New Hampshire, Vermont, New York, Pennsylvania, and Michigan) is about 35,000. The resulting venison at 20 cents per pound is worth considerably more than a million dollars. To this should be added the value of hides, trophies, and other products of deer. Bear also are killed in these States, and have a material annual value. Besides, in Maine, about 300 moose are killed annually, the meat, hides, and trophies of which are worth at least $25,000.

In the States west of the Mississippi Valley the game mammals comprise several kinds of deer, elk, moose, antelope, mountain sheep, mountain goat, and bear, and the annual kill is very large, but exact statistics as to numbers and values are lacking.

Game birds, including ducks and geese, snipe, plover, and other shore birds, and the various kinds of grouse and quail, are shot in great numbers in every State in the Union, and in the aggregate have an enormous food and pecuniary value.

The annual revenue from hunting licenses is large and is steadily growing. In 1907 resident licenses were required in 21 States, nonresident in 43. From the rapidity with which the license system is spreading, it is obvious that in a very few years it will be general and that the annual revenue from this source alone will exceed $3,000,000—a sum considerably in excess of that required for the support of an ample warden service; so that the returns from sale of licenses will be a source of direct revenue to the State.[a]

VALUE OF WILD FUR-BEARING ANIMALS.

North America was formerly the richest fur-producing region in the world, but now the stock of fur-bearing animals is greatly depleted, and the supply falls far short of the demand. Still, the annual export of raw furs from the United States is valued at from $7,000,000 to $8,000,000, and the furs retained for home manufacture reach an even higher figure, so that it is probably within bounds to say that the present value of the annual catch of furs in the United States is between $15,000,000 and $20,000,000. The growing scarcity of the more valuable fur bearers has produced in the lower grades a great increase in both demand and price. What is needed in the case of this group of mammals is wise husbanding of the wild stock, which everywhere is diminishing under the growing demand for furs and the rapid encroachment on their original domain by our ever-expanding civilization. Under proper restrictions, the stock of fur-bearing animals, particularly in mountainous regions and in the national forests, may, without cost for maintenance, be brought to yield a large annual revenue.

It is fortunate that one of the most valuable of the fur bearers, the silver fox, can be reared in a semidomesticated state, and it is believed that the industry of fox farming is likely to prove a permanent occupation in northern districts where the fur attains its best development.

LOSSES FROM DESTRUCTIVE RODENTS.

Another important lesson to be learned is the need of cooperative effort in reducing the numbers of the small rodents that prey upon our field and garden crops, nursery stock, and planted seeds. The annual losses to agriculture from the ravages of our native rodents—chiefly ground squirrels, gophers, rabbits, prairie dogs, and field mice—amount to about $37,000,000, to which must be added an even larger sum, estimated at nearly $56,000,000, for the losses caused by European rats and house mice. These small rodents—singly insignificant, collectively an unmitigated pest—are everywhere a steady drain on production, and in places threaten the very livelihood of the small farmer. To rid restricted areas of them is easy, but attempts to rid large areas often fail simply for lack of the necessary cooperation. As at present conducted the war against them is never ending, because when destroyed on a given tract others quickly come in from adjoining lands, so that the work must be repeated again and again, entailing large expenditures without permanent results.

---

[a] In Illinois the revenue from sale of licenses in 1907 was $145,905, exclusive of the cost of collection. In California the revenue from sale of licenses in 1907 was $118,427. The total sum actually available for game protection in 1905 was about $1,000,000.

LOSSES FROM THE LARGER CARNIVOROUS MAMMALS.

It has been estimated by stockmen that in Wyoming alone the losses from predatory animals—wolves, coyotes, and cougars—amount to $1,000,000 a year. This is about 3 per cent of the total value of the stock of the State. Assuming that the percentage of loss in the other States similarly infested ranges from one-tenth of 1 per cent to 2 per cent of the value of the stock, the annual loss to the United States is $13,844,000. This estimate does not include the value of game animals killed by carnivorous mammals, which aggregates several million dollars yearly. When the methods of destruction and repression recommended by the Biological Survey and put into practice by the Forest Service are extended over the wolf-infested country, about $7,000,000 may be saved annually.

This report shows that by the preservation and increase of our useful birds and game animals, and by the application of methods developed by the Biological Survey for the destruction of noxious species, millions of dollars may be saved annually; while the breeding of fur-bearing animals and the raising of deer and other game for market suggest what can be done by artificial means to increase natural resources now on the verge of exhaustion.

THE DEVELOPMENT OF GAME AS A NATURAL RESOURCE.

The game of the United States has never been systematically developed. The supply has usually been treated as inexhaustible, to be appropriated or destroyed at the whim of the individual, regardless of the future or the rights and interests of others, and only recently and in a few States has it been developed for the benefit of the people in general. The results of these wasteful methods are matters of common knowledge and are well exemplified in the case of the buffalo.

The actual destruction of the buffalo occupied less than twenty years, as shown by the following estimates of wild buffalo in the United States:[a]

1871 (Hornaday)	5,000,000
1889 (Hornaday)	285
1897 (practical extermination outside of parks)	---
1903 (Baker)	34
1908 (Hornaday)	25

---

[a] Including the wild herd in Yellowstone National Park as follows: 1889, 200; 1903, 34; 1908, 25.

These figures show clearly the rapidity with which an animal of commercial value may be practically exterminated. What is true of the buffalo is true also, though in less degree, of several other kinds of big game, and of the wild pigeon. Owing to an awakening of public sentiment, destruction has recently decreased to an appreciable extent, and some kinds of game are now more abundant than they were a few years ago. Low-water mark for game in general probably occurred in the early nineties, and is usually placed about 1895, since when, as a result of protection, most species have held their own or have even increased.

CAUSES OF DEPLETION.

The chief causes of depletion may be briefly summarized as: (1) Killing without provision for maintaining the breeding stock; (2) killing during the breeding season, or, in the case of migratory birds, en route to the breeding grounds; (3) killing without limit.

BETTERMENT.

The means of betterment of present conditions are clearly indicated by the causes of destruction just mentioned, and may be stated as follows: (1) Absolute protection during the period of reproduction, and, in the case of migratory game, during the spring journey to the breeding grounds; (2) careful adjustment of the open season so that the annual kill shall not quite equal the annual increase; (3) reasonable regulation of the methods and extent of killing; (4) provision for rearing game in captivity or otherwise, and for caring for wild stock during winter; (5) provision of adequate means for establishing and maintaining the work of game preservation.

The need for effective protection and the best means of securing it are well understood. The chief obstacle is one of finance, and this is being rapidly overcome by a system of hunting licenses which already has been put into successful operation in many parts of the country. The work has passed the experimental stage and has demonstrated not only that game protection can be made self-supporting, but that reasonably accurate estimates are possible as to the returns to be expected in almost any State. Omitting such centers of population as the great cities, it is safe to assume that from 3 to 5 per cent of the total population of the State will purchase licenses if a uniform $1 hunting license is in force. This will create a fund sufficient in almost every State to carry on the work. At least 12 States—Alabama, California, Connecticut, Idaho, Illinois, Michigan, Missouri, Montana, North Carolina, North Dakota, Washington, and Wisconsin—have already reached the point where the work of game protection is self-supporting. Similar results can be accomplished in most of the other States as soon as public sentiment has been awakened sufficiently to demand the necessary legislation. In 1905 the funds for game protection amounted to nearly $1,000,000, of which more than $500,000 was received from fees for hunting licenses, about $350,000 from specified appropriations, and the remainder from receipts from fines and miscellaneous sources.

To what extent game may be developed as a national resource can only be suggested by a few illustrations.

VALUE OF GAME.

The value of game may be direct or indirect. It may yield the State a direct revenue in the form of fees from hunting privileges and leases, and the owner a cash return from its sale for food, hides, trophies, and other products, or, if alive, for purposes of propagation; it may also directly increase the value of land. The principal indirect benefit is from the influx of nonresidents—hunters, photographers, and summer visitors—attracted by its presence, with the resultant employment of guides, boatmen, and camp help, and coincident increase of local business. The permanent financial benefit derived from this source has been thus summarized by Senator W. P. Frye:

> In all times of business depressions and distress, financial panics and consequent unemployment of labor, so seriously affecting the country, the State of Maine has suffered much less than any other State in the American Union, mostly, if not entirely, due to the large amount of money left with us by the fishermen, the summer tourist, and the fall hunter—the seeker after change, rest, and recreation.[a]

REVENUE FROM HUNTING LICENSES.

The modern system of hunting licenses in the United States practically began in 1895, and has been gradually extended until at present residents are required by nearly half of the States, and nonresidents by all but 5, to obtain licenses to hunt game. The price of a resident license is usually $1, while that of a nonresident license varies from $10 to $50. The rapid growth of the license system is shown by the fact that in 1903 resident licenses were required in 13 States, nonresident in 31; in 1905 resident licenses were required in 17 States, nonresident in 36; and in 1907 resident licenses in 21 States and nonresident in 43.

Receipts from these licenses have grown from inconsiderable amounts to large sums, which in several States are amply sufficient to support an efficient game warden force, and in a few to provide a large surplus available for the introduction and propagation of game. Thus in 1907 California collected more than $118,000 from the sale of hunting licenses, and Illinois about $145,905.[b] The returns for 1905, the latest year available, are shown in the table on the following page, which, for purposes of comparison, includes also the figures for 1903.

---

[a] Rept. Comm. Inland Fisheries and Game of Maine, for 1902, p. 21.

[b] Total receipts amounted to $191,943.50, from which have been deducted clerks' fees aggregating $46,038.50.

Number of hunting licenses issued and total fees collected in 1903 and 1905.

[a] No license in force.

[b] For rate and other details, see Circular 54, Biological Survey, United States Department of Agriculture, 1906, pp. 9, 13.

[c] Nonresident licenses inseparable from resident licenses.

Direct income from licenses.—In the States which have adopted both resident and nonresident licenses the percentage of licensed hunters in 1905 varied from one-fourth of 1 per cent of the population in South Dakota to more than 10 per cent in Montana, but in most of the States it was approximately 3 per cent. In every case in which the proportion was less than 1 per cent the falling off was evidently due to imperfect license laws. The figures in the foregoing table furnish the best basis at present available for estimating the total number of persons hunting in the United States and the amount of revenue obtainable under a uniform hunting-license law. The population of the United States, exclusive of Alaska, Hawaii, and Porto Rico, on June 1, 1905, as estimated by the Census Bureau, was 82,565,005. Three per cent of this number represents approximately the number of persons who hunt. In other words, the total number of persons who hunted in the United States in 1905 may be estimated at 2,500,000 to 3,000,000; hence if a uniform law requiring a $1 resident license had been in force in all the States the total revenue collected from this source would probably have been not less than $3,000,000.

ILLUSTRATIONS OF INCREASE IN VALUE OF LANDS DUE TO PRESENCE OF GAME.

Income from lease of hunting privileges.—In North Carolina shooting on another person's land without permission of the owner is prohibited by the game laws. Under this provision a system of leasing hunting privileges has grown up in certain counties during the last twenty years, especially in the north-central part of the State—in Davidson, Guilford, Forsyth, Moore, and Randolph counties. Owners of adjoining farms agree to permit no hunting on their land except by the lessee or his friends in consideration of the payment of a fixed sum or of all the taxes on the property included.

Guilford County, which may be taken as an illustration, has an area of 680 square miles, a little more than half that of Rhode Island. It contains two important towns, Greensboro and Highpoint. Its population in 1900 was about 40,000. On its farms, which average 100 or 200 acres in extent, wheat, corn, cotton, fruit, and vegetables are the principal crops. In 1904 about 150,000 acres, more than one-third the area of the county, was under lease for private game preserves, each preserve ranging from a few hundred to 12,000 or 15,000 acres. Some leases run for one year; others for five or ten years, with the privilege of renewal. The amounts paid for rental vary from 5 to 10 cents, based on the ordinary tax rate for lands outside the towns, which rate averages about 7 cents per acre. Recently a sum amounting to double the tax rate, or even more, has been paid by some lessees. More than one-third of the total real estate tax of the county, exclusive of that of the towns, is paid in this way by lessees of hunting privileges, who, in some cases, assume also special township school taxes. In other words, by merely keeping trespassers off their lands and uniting with their neighbors in leasing hunting privileges, farmers may be relieved entirely from real estate taxes and may perhaps, in addition, receive each year a substantial amount in cash.

Increase in value of marsh lands due to presence of game.—The marsh lands of California where ducks are abundant have greatly increased in value with the increase in popularity of duck shooting during the last fifteen years. In 1907 more than 100 clubs owned or leased game preserves for shooting purposes. The total area of these preserves is unknown, but it is probably not less than 160,000 acres, or approximately 250 square miles, and the preserves vary in size from a few hundred acres to 46 square miles. The capital invested probably amounts to $5,000,000 and comprises not only the value of the land (in case of ownership by the club), but also leases and such improvements as club houses, farms, and artesian wells, besides boats, arks, decoys, and other hunting paraphernalia. The value of the property may vary from a few hundred dollars, in case of leased grounds, up to a million dollars in case of grounds owned by a club which maintains a club house and develops the hunting facilities of the marsh to the highest degree possible.

Duck preserves in California comprise both fresh and salt water marshes, and may be roughly divided into six groups or districts. The two most important of these are the Suisun marshes on the north side of Suisun Bay, in Solano County, occupied by 12 or 15 clubs, and the marshes in southern California, in Los Angeles and Orange counties, occupied by some 36 clubs. Thirty of the southern California preserves have a combined area of about 40 square miles, and represent an investment approximating $3,000,000.

In 1893 one of the first clubs organized in the State leased 3,000 acres of land in the Suisun marshes for a term of four years at $1,200 per year, or an annual rental of 40 cents per acre. A few years ago a syndicate is said to have purchased 5,000 acres in the same marshes for $100,000, or $20 per acre; and four-fifths of this tract have since been sold or disposed of to members of shooting clubs at prices ranging from $40 to $50 per acre. Similar increases in values have occurred in southern California. In other words, lands suitable for duck preserves, which a few years ago were of little or no value, now command prices of $40 per acre and upward, and the improvements on such property in several instances aggregate thousands of dollars.

Annual kill of big game in the northeastern States.—Moose and deer are the only big game animals which can now be killed east of the Mississippi River. Moose hunting is permitted only in Maine and Minnesota, and deer hunting north of the Mason and Dixon line only in Maine, New Hampshire, Vermont, New York, Pennsylvania, Michigan, Wisconsin, and Minnesota. Statistics of the actual number of moose and deer in any State, or of the annual increase, are not available, and only one State—Vermont—publishes a record of the number annually killed. Statistics of the shipment of big game are collected in Maine and New York, however, and from these, and from other data for Pennsylvania and Michigan, it is possible to estimate the number annually killed in several of the States.

Figures for the decade from 1897 to 1906 are as follows:

Number of moose shipped in Maine (Bangor and Aroostook Railroad).

1897	139	1902	224
1898	202	1903	232
1899	166	1904	222
1900	210	1905	207
1901	259	1906	198

Number of deer killed or shipped in four States.

Year.	Deer killed.		Deer shipped.				
			Maine.		New York (Adirondacks).		
	Vermont.	Michigan (estimated).	Bangor and Aroostook Railroad.	All roads.[a]	Carcasses.	Saddles.	Heads.
1897	103	....	2,940	....	....	....	....
1898	131	....	3,377	....	....	....	....
1899	130	....	3,756	....	....	....	....
1900	123	2,000	3,379	....	1,020	89	95
1901	211	6,000	3,882	6,233	1,062	103	121
1902	403	....	4,495	....	1,354	113	193
1903	753	22,000	3,786	5,853	1,961	145	188
1904	531	7,000	3,558	5,475	1,618	124	152
1905	497	7,000	4,634	6,799	2,196	108	180
1906	634	10,000	3,377	5,494	2,413	108	102

[a] Statistics from the Maine Sportsman.

Explanation of the table.—Statistics of the amount of game killed, as an index to relative abundance, are not always directly comparable, even in adjoining States, for the reason that the three factors of length of season, bag limit, and license fees may conceal or exaggerate differences in the returns from different States, or the fluctuations from year to year in the same State. For example, the deer season in Vermont lasts 6 days, that in Maine 76 days; in Vermont each hunter may kill one deer, while in Maine each may kill two; residents of Maine and Vermont may hunt without a license; in Michigan each must pay $1.50 for the privilege.

Vermont.—As an illustration of the effects of protection and restocking, the statistics of deer killed in Vermont are the most accurate and interesting of any in the United States. Thirty years ago deer in Vermont had been practically exterminated, except in the extreme northeastern corner (in Essex County). About this time a few deer were liberated in the southern part of the State, and these two centers (Essex and Rutland counties) have supplied the stock which has now spread over the State. Deer hunting was prohibited for a number of years, the first open season being that of 1897. The table indicates that from 1897 to 1906 the annual kill increased more than 600 per cent. The actual abundance of the animals must also have greatly increased, for the open season, originally the entire month of October (1897–1898), was shortened after 2 years to the last 10 days in October (1899–1903), and 4 years later to the last 6 days in October (1904–1906). Moreover, since 1904, nonresidents have been required to pay a license fee of $15, and the number of visitors from other States who formerly visited Vermont to hunt deer may have been reduced in consequence of this additional expense.

Michigan.—Fluctuations in the figures for Michigan are due to a combination of causes, artificial as well as natural. In 1900 the season opened with sufficient snow for tracking, and in consequence large numbers of deer were killed. In the following year changes in the game law prohibited sale and reduced the number of deer allowed each hunter to three. These circumstances explain in large measure the reduction of 50 per cent in the number of deer killed. The falling off in 1904 was due to a light snow, and that in 1905 to the same cause, and probably also to the fact that the cost of the resident hunting license was doubled.

Maine.—The only statistics available for a period of years are those for shipments over the Bangor and Aroostook Railroad. But in recent years data are available from other railroads also, and these indicate that the returns from the Bangor and Aroostook Railroad should be considerably augmented to represent the total number of deer shipped in the State. For example, in 1905 and 1906 the figures for the Bangor and Aroostook Railroad are 4,634 and 3,377, respectively, while those for all the roads are 6,799 and 5,494, respectively.

New York.—In New York the deer shipments from the Adirondacks are reported as carcasses, saddles, and heads, but it is impossible to tell exactly how many deer are shipped, for the reason that a saddle and a head may or may not represent parts of the same animal. In addition to the deer killed in the Adirondacks, a few are obtained in other counties, and about 50 or 100 annually on Long Island. In 1895 and 1896 the fish, game, and forest commission reported the total number killed in the State at 4,900 and 5,247, respectively, but in recent reports the annual kill is not estimated. In view of the fact that since 1895 shipments have more than doubled, 5,000 may be accepted as a conservative estimate of the number killed in 1906.

Estimates of annual kill of deer.—Estimates of the number of deer killed in 1906 in Maine, Vermont, Pennsylvania, and Michigan have been made by the state game commissioners. It is probable that the number killed in New York is not less than 5,000, and that in New Hampshire the season's yield is approximately the same as that in Vermont. On this basis the total number of deer killed in these six Northern States is about 35,000, as follows: Maine, 18,000; New Hampshire, 600; Vermont, 634; New York, 5,000; Pennsylvania, 800; Michigan, 10,000. Total, 35,034.

Value of venison.—Assuming the average weight of a dressed deer to be 150 pounds,[a] the total quantity of venison produced in these six States in 1906 was about 5,255,000 pounds. At an average value of 20 cents a pound this would be worth $1,051,000.

FINANCIAL BENEFITS ACCRUING FROM PRESENCE OF HUNTERS AND SUMMER VISITORS.

In 1902 the commissioners of inland fisheries and game in Maine endeavored to ascertain the number of nonresidents who visited the State (exclusive of seaside resorts) for the purpose of fishing, spending vacation, or hunting, and the amount of money left in the State by such visitors. Of sixteen counties in the State, no returns were received from Lincoln and Sagadahoc, and only incomplete returns from Aroostook, Franklin, Penobscot, Piscataquis, Somerset, and Washington. According to the statistics collected, the visitors in 1902 numbered 133,885, and paid for board $1,371,201 and for guides $300,000. Their presence involved the employment of 3,965 persons—1,401 males and 2,564 females. The figures for receipts, wages, and capital invested are as follows:

Receipts, wages, and capital invested on account of summer visitors in Maine, 1902.

Cash received for board of visitors	$1, 371, 201
Wages for male help	153, 541
Wages for female help	114, 398
Value of boats, canoes, and launches	815, 048
Money invested in summer hotels, cottages, and hunting camps	5, 541, 274

Statistics of the amount of money paid for railroad, electric car, and steamboat fares, for team hire, and for other purposes are not available. The commissioners add:

> It is believed that a most conservative estimate would be that these visitors leave at least $100 each, on an average, in the State. Indeed, some of them spend more than $50 a day, and a good many of them spend several thousand dollars each year.

---

[a] That these estimates are conservative is shown by the fact that the average weight of dressed deer killed in Vermont in 1905 was 198 pounds, while in New York the heaviest bucks occasionally weigh 265 or rarely 285 pounds. The value of venison varies greatly with the market where it is sold.

It will be seen, therefore, that if they spend on an average $100 each, over $13,000,000 are left by them in Maine each year; or if they spend but $50 each they leave six millions and a half of money with us annually. (Rept. Comm. Inland Fisheries and Game, 1902, pp. 34–35.)

FARMING DEER AND OTHER GAME.

As a result of the growing scarcity of game the supply of venison and game birds is wholly inadequate to the demand, and the time seems to have arrived for the propagation of game on private preserves or game farms.

The raising of venison and game birds for market is as legitimate a business as the growing of beef and mutton, and state laws when prohibitory, as many of them are, should be so modified as to encourage the industry of game breeding. Deer and elk may be raised to advantage in forests and on rough bushy ground unfit for either agriculture or stock raising, while ducks and other waterfowl may be bred on otherwise valueless marshes, so that large areas of waste land may be utilized for profit. An additional advantage is that the business is well adapted to landowners of small means. Besides supplying game for market, breeders of game mammals and birds may find even greater profit in raising them for stocking preserves. For many years to come the demand for this purpose is likely to exceed the supply.

VALUE OF FUR-BEARING ANIMALS.

The United States, with Alaska and outlying islands, forms a large part of what was once the richest fur-producing region in the world. Its present output is still large, but it is obtained with increasing difficulty and the future is very uncertain. Excepting the arid and treeless parts of the West, practically all the territory now included in the United States was inhabited originally by animals bearing valuable pelts. In the Eastern States these animals were speedily reduced in numbers or driven to less accessible regions, and their pursuit as a business soon passed to the Western and Northern States.

With the purchase of Alaska in 1868 the United States became more than ever identified with the fur trade, for in addition to great quantities of less important kinds this great territory produced a majority of the world's supply of fur seal and sea otter skins and a considerable proportion of silver-black fox, three of the most valuable of furs. But even in Alaska the pace set was too rapid, and the natural increase of the animals failed to keep up with it.

Although the ranges of the more important fur-bearing animals have become more and more restricted, and the animals themselves have rapidly diminished in numbers, still the annual volume of trade as expressed in dollars and cents has remained remarkably uniform, even showing a tendency to increase. Thus the exports of raw furs in 1890 amounted to $4,661,934, in 1895 to $3,923,130, in 1905 to $6,599,222, and in 1906 to $8,002,282. For the twenty-five years from 1875 to 1900 the average annual export value of furs was more than $4,000,000, the total for this period, therefore, being over $100,000,000. These figures are explainable only by the fact that many furs have doubled, trebled, and even quadrupled in price; so that, although total receipts do not fluctuate greatly, the number of pelts marketed annually is much smaller than formerly.

As indicating the extent of the annual fur trade in the United States, the following table is given, being an estimate of the number and value of certain of the more important furs produced in the United States during 1900:[a]

Designation.	Number of skins.	Value.
Beaver	8,000	$39,80
Fur seal	24,000	660,00
Mink	578,000	810,60
Muskrat	4,035,000	565,00
Otter	14,600	93,29
Sea otter	330	133,98
Total value		$2,302,18

The accompanying table shows the value of furs exported yearly from the United States since 1890:

Value of furs exported from the United States, 1890–1907.[a]

Year.	Value.	Year.	Value.	Year.	Value.
1890	$4,661,934	1897	$3,284,349	1904	$5,422,954
1891	3,236,705	1898	2,986,970	1905	6,599,222
1892	3,586,330	1899	3,092,846	1906	8,002,282
1893	3,699,579	1900	4,503,968	1907	7,139,221
1894	4,238,690	1901	4,404,448		
1895	3,923,130	1902	5,030,204	Total exports, 1890–1907	$83,794,115
1896	3,800,168	1903	6,181,115		

[a] From Commerce and Navigation, Bureau of Statistics, U. S. Dept. Commerce and Labor.

Average annual value for these eighteen years, $4,655,228.

INCREASED DEMAND FOR AND PRODUCTION OF LOW-GRADE FURS.

That the supply of the better grades of furs is unequal to the present demand is proved not only by the higher prices they bring, but also by the steady increase in the quantity of cheaper furs used and by the additional fact that these cheap furs have gradually brought higher and higher prices, until now they command prices equaling or exceeding those formerly paid for better furs. Very large quantities of cheap furs are manufactured in the United States, in addition to those sold in the London market, but statistics of the home-manufactured product are not available.

The fur of skunks, for example, was practically unnoticed prior to 1850. In 1851 the Hudson Bay Company offered 1,453 skunk skins for sale, and for twenty years the annual number sold was scarcely more than 10,000. In 1891 the number had increased to upward of 400,000, and the increase, both in number and price, has continued to the present time, the number reaching 1,368,475 skins in 1907, as shown by the following table:

---

[a] From Ann. Rept. U. S. Comm. Fisheries, 1902, p. 287.

Skunk fur sold in London market.[a]

Year.	Number of skins.	Advance in price.	Decline in price.

[a] Compiled from London sales. [b] Stationary. [c] No report.

Muskrat fur has been in use much longer than skunk, but for years was little valued. Now it has been computed that about 5,000,000 animals are killed annually. The total product of this fur in the United States is now worth at least $1,000,000 annually.

Increased prices have given greater incentive to the pursuit of fur-bearing animals, so that the work of extermination begun decades ago has progressed in recent years with greater and greater rapidity. The most conspicuous examples of rapid decrease are those of the sea otter and the fur seal. From 1873 to 1885 the annual catch of sea otters in Alaskan waters was from 3,000 to 4,000 skins. Estimating these conservatively as worth $300 each, the total yearly value was about $1,000,000. In 1895 the catch had dropped to 887, and in 1905 to 320, a decrease of approximately 90 per cent in twenty years. The Pribilof fur seals, which once yielded millions of dollars, have decreased enormously during the past twenty years. Thus the average yearly catch on the islands from 1868 to 1889, inclusive, was

104,834, while for the years 1904–1906 it averaged 13,249. In other words, an important source of revenue in a region otherwise unproductive is gradually being destroyed.

Comparison of the value of the total shipment of furs from Alaska for the past five years, 1903–1907, with the figures for corresponding previous periods, emphasizes the fact that the actual number of furs formerly exported annually was so much greater than now that even at the comparatively small prices then prevailing the value of the exports for each of the two periods from 1881 to 1885, inclusive, and from 1886 to 1890, inclusive, was practically five times as great as during the past five years.

Shipments of furs from Alaska.

DECREASE AND REMEDIES.

Accurate figures showing the rate of decrease of the wide ranging smaller fur-bearing animals are not obtainable, but most of these animals are everywhere greatly reduced in numbers, and throughout a large part of their original range are practically extinct. The beaver, for example, which was formerly abundant over three-fourths of North America, is now extinct in more than half of this area, and over the remainder occurs only in relatively small numbers. In 1870 the number of beaver skins exported from North America was approximately 225,000; in 1890 it had diminished to 82,000. Other fur bearers, as foxes, martens, fishers, and land otters, are similarly decreasing, as shown by the number of skins exported.

Throughout the length and breadth of coniferous forests of the Rocky Mountains from Montana to New Mexico, and of the Sierra-Cascade Range from the State of Washington to southern California, fur-bearing animals were formerly so abundant as to form the principal source of revenue to the early explorers and settlers. Now they are so scarce as to be unimportant. The cause of this great decrease over more than 150,000,000 acres of our public domain is not so much overtrapping as overgrazing. Overgrazing by sheep has converted many thousands of miles of brushy slopes and mountain meadows into barren deserts, destroying the cover which sheltered the hordes of small mammals and birds on which the fur bearers subsist.

The practical extinction of fur-bearing animals in areas suitable for settlement and for the development of agriculture or manufacturing is inevitable, but in areas not needed for the development of industries there is no necessity for their utter depletion. The greater part of the vast territory of Alaska and thousands of square miles of national forests, national parks, and other wild forest lands in the United States when not injured by overgrazing offer ideal conditions for the continued existence of these species. These animals, if fostered in such regions, will not only prove a valuable asset in themselves but in many localities will add to the value of the forest, for most of them prey upon the insects and gnawing animals which are constantly at work injuring trees and devouring seeds on which the future life of the forest depends.

The remedy seems to lie in the prevention of overgrazing and in the enactment of laws limiting the open season for trapping. Many of the States have already realized the necessity for such legislation and have acted accordingly. It remains only for other States and the National Government to follow their example in order to provide for the preservation and utilization of an important natural resource which, at no cost for maintenance, may be made to yield a substantial annual revenue.

A good example of such protective laws is the one passed by the State of Michigan in 1897, extracts of which are here given.

AN ACT For the protection of certain fur-bearing animals.

[Act 86, P. A. 1897.]

The people of the State of Michigan enact:

(518) Paragraph 5825. SECTION 1. It shall not be lawful for any person or persons to trap, catch, kill, or destroy, or attempt to trap, catch, kill, or destroy, by any means whatsoever, any beaver in this State until the thirty-first day of December, nineteen hundred ten.[a]

(519) Paragraph 5826. SEC. 2. No person shall hunt, trap, catch, kill, or destroy, or attempt to hunt, trap, catch, kill, or destroy, within this State, by any means whatsoever, any otter, fisher, or marten, from the first day of May in each year to the fifteenth day of November following thereafter.

(520) Paragraph 5827. SEC. 3. It shall be the duty of every person having knowledge or information that acts amounting to a violation of this act have been committed to at once report the same to the State game and fish warden, or to the deputy game and fish warden residing in or having supervision over the county wherein the alleged violation was committed, or to the prosecuting attorney of such county, whose duty it shall be to forthwith prosecute the offender.

(521) Paragraph 5828. SEC. 4. Any person who shall be found guilty of a violation of any provisions contained in the foregoing act shall, upon conviction thereof, be deemed guilty of a misdemeanor, and be punished by a fine of not less than ten dollars, nor more than fifty dollars, and the costs of prosecution, or imprisonment in the county jail not to exceed ninety days, or both such fine and imprisonment, in the discretion of the court.

AN ACT to protect mink, raccoon, skunk, and muskrats during the months of September and October in each year, and to provide a penalty for the violation thereof.

[Act 201, P. A. 1899.]

The people of the State of Michigan enact:

(522) SECTION 1. That it shall not be lawful for any person or persons to trap, hunt, shoot, or kill any mink, raccoon, skunk, or muskrat in this State during the months of September and October in each year; (*a*) except it be on his own premises, and such person can prove that the said animal was damaging him: *Provided, however*, That this act shall not be construed so as to repeal act number twenty-seven of the session of eighteen hundred ninety-seven; *Provided further*, That nothing in this act shall prevent water-power owners from

---

[a] Am. 1905, act 204.

killing or destroying muskrats within one-half mile of any water power in this State: *And provided also*, That nothing in this act shall be construed to prevent owners of dykes from killing or destroying muskrats on or along such dykes when damaging such dykes.

(523) SEC. 2. Any person who shall be found guilty of violating any of the provisions of this act shall, upon conviction thereof, be deemed guilty of a misdemeanor, and shall be liable to a fine of not more than one dollar and costs of prosecution for each and every animal killed.

ECONOMIC RELATIONS OF BIRDS.

So important are birds as conservators of the forest and as protectors of farm crops that neither forestry nor agriculture could be successfully practiced without their aid. As year by year the value of farm and orchard products increases, so the value of birds as conservators of the farmers' interests increases. The need of adequate legislation in favor of insectivorous birds was never so great as now, and it is probable that in the future protective laws will be still more important. Insectivorous birds spend their lives in the pursuit of insects, vast numbers of which are required for their support. The seed-eating birds attack noxious weeds at the most critical stage of their existence, during and after seeding, and as seeds constitute for these birds the staff of life the quantity they destroy is incalculable. No labor-saving machine has ever been devised that equals the value to the farmer of the seed-eating birds. The predatory birds, mainly hawks and owls, render an even greater service, keeping down the hordes of mice, gophers, ground squirrels, and other vermin that destroy crops. It is not too much to say that such outbreaks as the recent field-mouse plague in Nevada would never occur were it not that our predatory animals have been so greatly reduced by ruthless killing that they are no longer able to prevent the increase of these pests.

A good illustration of the costliness of popular misconceptions as to the economic status of some of our common birds and mammals may be found in the so-called "scalp act" of Pennsylvania, passed in 1885. This act provided a bounty of 50 cents each on hawks, owls, weasels, and minks killed within the state limits and a fee of 20 cents to the notary or justice taking the affidavit. As a result about $90,000 was paid in bounties during the year and a half subsequent to the passage of the act. This amount represents the destruction of at least 128,571 of the above-mentioned animals, most of which were hawks and owls. Estimating that 5,000 chickens are annually killed in Pennsylvania by hawks and owls, and that their value is 25 cents each (a liberal estimate in view of the fact that a large proportion of them are killed when very young), the total loss of poultry in a year and a half would be about $1,875. It thus appears that $90,000 were paid by the State of Pennsylvania to save its farmers a loss of less than $2,000. But this estimate by no means represents the actual loss to the farmer and taxpayer of the State. It is safe to say that every hawk and owl yearly destroys at least 1,000 mice, or their equivalent in insects, and that each mouse or its equivalent so destroyed would cause the farmer a loss of 2 cents per annum. Thus the lowest possible estimate of value to the farmer of each hawk and owl would be $20 a year. The actual loss to the State, therefore, by the destruction of 128,571 of its benefactors in a year and a half was about $3,850,000. Even these figures, enormous as they are, do not represent the entire loss to the State, since the destruction of such a vast number of predaceous birds and mammals is sure to be followed by a corresponding increase in the number of mice and insects, their natural prey, and years must elapse before the balance of nature thus destroyed is restored.

LOSSES FROM CARNIVOROUS MAMMALS.

Wolves are still numerous in parts of Wyoming, Montana, the Dakotas, Nebraska, Kansas, Colorado, New Mexico, Arkansas, Oklahoma, Missouri, Michigan, Wisconsin, and Minnesota, and yearly destroy great numbers of cattle and horses. Coyotes are numerous over a still larger area and destroy vast numbers of sheep, while cougars, or mountain lions, in certain parts of the West kill annually so many colts that they must be reckoned with as an economic factor of considerable importance.

Bounties have had little effect in exterminating predatory animals, or even in permanently reducing their numbers. Thus, in Wyoming, where liberal bounties for wolves and coyotes have been paid for the past twelve years, both animals are still numerous. This is shown by the following table:

Bounty records for twelve years in Wyoming.

Year.	Number of wolves on which bounty was paid.	Bounty per wolf.	Total amount paid in bounties.
1895	1,699	$3	$5,097
1896	3,365	3	10,095
1897	897	4	3,588
1898[a]	....	....	....
1899 and 1900[b]	4,908	3	14,724
1901 and 1902[b]	4,480	3	13,440
1903 and 1904[b]	2,256	5	11,280
1905 and 1906[b]	3,214	3	9,642
Total for 11 years	20,819	....	67,866

[a] Species not reported separately; $14,160.25 paid on wolves, coyotes, and mountain lions.
[b] Biennial reports not separated by years.

In 1906 Mr. Victor Culberson, president and manager of the G. O. S. Cattle Company, on the Gila Forest Reserve, Grant County, N. Mex., estimated the loss of cattle killed by wolves to be 10 per cent of the herd. This loss was sustained under a bounty system of $20 per head for wolves, as shown in the following table:

Bounty records for four years in Grant County, N. Mex.

Year.	Number of wolves on which bounty was paid.	Bounty per wolf.	Total amount paid in bounties.
1902	11	$20	$220
1903	33	20	660
1904	54	20	1,080
1905	29	20	580
Total for 4 years	127	....	2,540

Although no exact figures are available, the following estimate is probably not far from the truth and is at least safely conservative:

A prominent stockman of Wyoming estimates the losses from predatory animals in that State at $1,000,000 a year, or about 3 per cent of the total value of the stock of the State. Assuming that the percentage of loss in other States infested by wolves, coyotes, and cougars ranges from one-tenth of 1 per cent of the value of the stock to 2 per cent (the estimate being made from known conditions), the annual losses aggregate as follows:

Range cattle	$5, 889, 000	
Horses and mules	1, 636, 000	
Sheep	4, 152, 000	
Hogs	584, 000	
Goats	83, 000	
		$12, 344, 000
Poultry (by coyotes, wildcats, foxes, mink, weasels, etc)		1, 500, 000
Total		13, 844, 000

This estimate does not include the game animals destroyed by carnivorous mammals, the value of which aggregate several million dollars yearly.

Thus the combined losses of stock and wild game from predatory mammals, especially from wolves and coyotes, amount to many millions annually. The extermination of these animals under present conditions is not possible, nor indeed is it necessary, since by energetic and concerted action throughout the infested States their numbers can be permanently reduced and the losses kept down to a minimum, with or without the offering of bounties. It is safe to say that by the methods recommended by the Biological Survey, and actually put into effective operation in and adjacent to the national forests by the Forest Service, fully half this loss, about $7,000,000, may be saved each year.

LOSSES FROM RODENTS.

Prairie dogs.—Prairie dogs infest most of the open plains country of the United States from near the Canadian boundary south into Mexico, and from a little east of the one hundredth meridian westerly to the foot-hills of the Rocky Mountains, and also a considerable part of the plateau country still farther west. Their colonies—"dog towns," as they are commonly called—vary in extent from a few acres to thousands of square miles and are inhabited by thousands and in some cases by millions of animals. Colonies 20 to 30 miles in length are not rare, and in Texas one is known which measures 250 miles one way by 100 to 150 the other, covering an area of about 25,000 square miles. The number of holes in use in each acre varies from a few to upward of a hundred, and probably averages at least 25. In winter and early spring the usual number in each hole is two (a pair), while after the birth of the young the number is at least quadrupled, and then decreases with the advance of the season, as the young are killed by their enemies. It is certainly a conservative estimate to assume the average number of animals per acre to be 25. On this assumption, the number of prairie dogs in the great Texas colony must be at least 400,000,000.

It is estimated that 32 prairie dogs consume as much grass as 1 sheep, and 256 prairie dogs as much as 1 cow. On this basis the grass annually eaten by these pests in the great Texas colony would support 1,562,500 head of cattle. It is no wonder, therefore, that the annual loss from prairie dogs is said to range from 50 to 75 per cent of the producing capacity of the land and to aggregate millions of dollars. The annual rental value of range land for grazing purposes is from 8 to 15 cents per acre. At an average damage of 5 cents per acre the loss amounts to $1,500,000 per year. But grass is by no means the only crop injured by prairie dogs, for they are extremely destructive also to grain and other products of the soil. The annual loss to farmers from this source probably reaches $1,000,000, making the total annual loss about $2,500,000.

In the open grazing regions where natural conditions prevail prairie dogs usually increase slowly and do not extend their range rapidly. But the settlement of an infested district usually results in a large increase of the food supply and is followed by a rapid extension of range and great increase in the numbers of the pests. Even in areas where they were not particularly numerous previous to the arrival of the farmers, they soon become so abundant that without some cheap and successful method of destroying them profitable agriculture becomes impossible.

In the State of Kansas in 1901, 2,500,000 acres were occupied by prairie-dog colonies. Here as elsewhere the animals damaged the pasture fully 50 per cent, the actual loss amounting to half the rental value of the land, which ranged from 4 to 12 cents per acre. The annual loss to the cattle owners of the State was estimated at $100,000, and the loss to crop producers at nearly as much more. In 1902 the State took the matter in hand and organized a campaign of extermination. The State furnished poison at cost of manufacture, and the work was done under township supervision, the funds being raised by taxation. The total expense, distributed over five years (1902–1906), was about $85,000, or slightly more than 4 cents per acre, as a result of which the prairie dogs were destroyed on at least 2,000,000 acres of infested land.

The good effects on the pasturage were apparent the first year after the prairie-dog town was destroyed, especially where the mounds were leveled. New grass came in on the bare spots and grew luxuriantly. Cattle preferred the parts of the pasture where the "dog town" had been located; whereas when the dogs were present these had been carefully avoided. The sustaining capacity of the land was greater than ever before and a large increase was noted in the selling value. The annual saving to the people of western Kansas is fully double the total cost of the entire work of extermination. It is obvious, therefore, that by the systematic use of well-tried methods over the country now suffering large annual losses from prairie dogs the total of these losses may be easily reduced by at least $1,000,000.

Ground squirrels.—Ground squirrels occur almost everywhere from the Mississippi Valley to the Pacific Ocean, and one species ranges east to Indiana and southern Michigan. The extent of the area they inhabit collectively is about 1,900,000 square miles, or 1,216,000,000 acres. The more destructive species occupy about 825,000 square miles, or 528,000,000 acres, of which 115,000,000 acres are in crops and 413,000,000 acres in range and waste lands.

Ground squirrels rank among the most destructive of North American mammals, causing an annual loss to grain and other crops of about $10,000,000, fully half of which may be saved by the general adoption of methods of poisoning and trapping recommended by the Biological Survey.

The present annual losses in the infested States of the Missouri-Mississippi valley vary from less than 1 per cent to 2 per cent of the grain crop; but in the Sandhills region of western Nebraska and Kansas the loss is so great that in places it is hardly worth while to plant. From Montana and Colorado westward to Washington, Oregon, and California the loss amounts to from 2 to 10 per cent of the value of the grain crop.

Besides the injury to cultivated crops, ground squirrels where abundant do considerable damage to grazing lands by eating the grass and covering it with mounds. This loss is not included in the above estimate of $10,000,000.

The economy of destroying ground squirrels on agricultural lands is not open to question. By the use of poisoned grain and poisoned alfalfa the smaller species are easily killed, at an average cost, including necessary labor, of about 4 cents per acre, or $25 a section. The wheat or barley crop on a section of land in the State of Washington, where the Townsend ground squirrel is abundant, is worth on an average $15 an acre, or $9,600 a section. In badly infested areas the squirrels destroy 10 per cent of the crop, worth $960. By the expenditure of $25 the owner of the section can save $935 the first year and $960 annually for the three or four succeeding years, or until the animals again become abundant.

The cost of destroying the larger species is considerably greater, but, allowing for the difference in expense, the saving on grain would scarcely fall below $800 a section.

On range lands, however, the case is very different, and the economy of destroying the squirrels is doubtful. It has been estimated that 500 of the smaller ground squirrels consume as much grass as a horse or cow. Allowing 10 squirrels to the acre, their destruction would permit the pasturage of an additional horse or cow to each 50 acres. The detriment to the range by squirrels, when abundant, is about 20 per cent of the sustaining capacity. Placing the average rental of the range at 5 cents an acre for the season, the loss amounts to 1 cent an acre. As the destruction of squirrels costs 4 cents an acre, it would require four seasons of freedom from the pests to recover the outlay. Unless, therefore, the work were undertaken on a large scale, by cooperation, so as to secure lasting results, the investment would not pay. However, since range and waste lands are the source from which cultivated fields are restocked with rodent pests, it would undoubtedly pay to destroy the squirrels on ranges adjacent to cultivated crops.

Pocket gophers.—Pocket gophers are distributed over about 1,800,000 square miles of territory in the United States, chiefly from the eastern part of the Mississippi Valley westward. Of this area about one-tenth is in farm crops, from which are derived returns of about $1,500,000,000 yearly. It is estimated that the losses caused by pocket gophers amount to $12,625,000 a year, as follows:

Loss on alfalfa	$4,000,000
Loss on native hay	2,500,000
Loss on clover and tame grasses	3,000,000
Loss on orchard and other trees	1,750,000
Loss on gardens and crops not included above	575,000
Damage to machinery and embankments	800,000
Total loss	12,625,000

Permanent crops, rather than annual ones, are most subject to injury from gophers, and the damage to corn and small grains is comparatively slight. Gophers devour potatoes, sweet potatoes, melons and cotton, but the chief damage they do is to the hay crop and fruit trees. Their favorite food is alfalfa and clover, which they destroy in two ways—by devouring and by burying. The mounds of earth thrown up in meadows cause heavy losses by covering up the grass and preventing close mowing. Where gopher mounds are abundant, from 10 to 20 per cent of the hay is lost.

The alfalfa growers of the Middle West outside of irrigation districts are the most serious losers from pocket gophers. Statistics of the acreage in alfalfa in most of the States are lacking, but two States, Kansas and Nebraska, will serve for illustration. In 1907 Nebraska had 455,792 acres of alfalfa, producing 1,450,759 tons of hay, which at $5 a ton was worth $7,253,795; Kansas had 743,050 acres of alfalfa, which at the same yield and price was worth $11,800,000. It is estimated that in Kansas pocket gophers compelled farmers to leave 10 per cent of their crop on the ground, and conditions in Nebraska were about the same. It is safe to conclude, therefore, that the loss from gophers in these two States in 1907 amounted to at least $2,000,000.

Throughout the greater part of the upper Mississippi Valley and the whole of the Missouri Valley clover, timothy, and native meadows are infested with gophers, whose mounds cause an average loss of 4 per cent of the hay crop, or a total of over $5,000,000 yearly.

The cost of destroying pocket gophers by poisons is not great. A 40-acre field of clover or alfalfa can be cleared of them at an expenditure of less than $5. Trapping is an excellent though slower method, requiring less outlay aside from labor. The feasibility of destroying gophers has been repeatedly proved, but cooperation over large areas is necessary to secure permanent results.

Field mice.—Short-tailed field mice are generally distributed throughout the grassy and mountainous parts of the United States. Under normal conditions they are among the commonest of rodents and cause losses to agricultural crops and fruit trees exceeding $3,000,000 annually.

In the Old World mouse plagues, differing in intensity, have often occurred and have resulted in widespread destruction. The most recent irruption was in France in 1904, where a considerable part of the loss of $40,000,000 attributed to rats and field mice was due to the latter animals. Until recently no plagues of similar severity have occurred in the United States, but in 1907 field mice increased enormously in various parts of the great basin region, especially in Humboldt Valley, Nevada, where over a considerable area they reached a total of 8,000 to 12,000 per acre. As a consequence 15,000 acres of alfalfa out of the 20,000 in the valley were a total loss, so that the fields had to be plowed and resown. The loss of hay, pasturage, root crops, trees, and the wheat crop for 1908, and the cost of replanting the alfalfa fields amounted to about $20 per acre, or a total for the valley of $300,000.

When the numerous irrigation schemes now on foot are completed, a very large additional acreage will be placed under alfalfa, and unless due precautions are taken a repetition of the Nevada mouse plague is almost certain, since extensive fields of alfalfa, offering the mice shelter as well as sustenance, furnish ideal conditions for their excessive multiplication.

Field experiments by the Biological Survey show that meadow mice are among the easiest mammals to control by poisoning. Under the most favorable conditions two or three years are necessary for them to increase to an actual plague, and during this time they can be effectually destroyed at a cost varying from 10 to 20 cents per acre, according to the degree of infestation; while 40 cents per acre is estimated to be the average cost of destruction after they have become a plague. Thus from a purely economic standpoint it is much cheaper to attack them whenever they show an increase than to wait until they have become excessively abundant. On alfalfa lands yielding gross returns of $50 per acre, the damage done by field mice under normal conditions of abundance amounts to $1 to $2 per acre. Almost the whole of this loss can be prevented at a cost of from 10 to 20 cents per acre, thus saving annually from 90 cents to $1.80 per acre.

Even this expenditure, small as it is, would be unnecessary providing due regard had been paid to the protection of such birds as hawks, owls, gulls, and herons, and of such mammals as foxes, coyotes, badgers, weasels, and skunks—nature's own agents in checking the abnormal increase of small rodents. The Nevada outbreak of mice was the signal for the assembling of mouse-eating birds and mammals in numbers quite sufficient, after the mice had been reduced to something like their normal number, not only to hold them in check but to reduce their numbers far below the normal. It is practically certain that the Nevada plague would never have occurred had not predaceous birds and mammals been so reduced as to be quite inadequate for the service they are always eager to perform. Predatory birds and the smaller predatory mammals are an important part of the national assets, and can not be wantonly destroyed without incurring serious consequences.

House rats and mice.—The most destructive mammalian pests in the United States are the European house rats and mice. They were introduced into America so long ago that they are thoroughly acclimatized and range over nearly the whole cultivated parts of our territory, though much more abundant and destructive in towns and cities than in the country.

Every rat in the course of a year destroys property probably worth from 50 cents to a dollar. From investigations in Washington and Baltimore during the past year it is estimated that the annual losses from rats and mice to merchants and manufacturers in cities having a population of 100,000 or more, amount to $20,000,000. The losses from the destruction of grain, poultry, eggs, and other produce on farms, in villages, and in private residences throughout the country amount to a still larger sum. Injury to buildings, furniture, and fixtures, and the cost of fighting the pest by traps, poisons, dogs, cats, ferrets, and professional rat catchers add materially to the above totals. In the absence of accurate statistics for the United States, estimates of the damage done in other countries are of interest. In Denmark the annual loss from rats is put at $3,000,000; in Great Britain from $25,000,000 to $50,000,000, and in France, in 1904, the loss from rats and field mice was estimated at $40,000,000. These figures are suggestive, in view of the fact that the United States, not including Alaska, has 35 times the area of Great Britain, 15 times the area of France, and 200 times that of Denmark.

The importance of killing rats is greatly increased by the fact that these animals are known to be carriers of vermin and disseminators of bubonic plague and other diseases. In Athens, Odessa, Oporto, Glasgow, and other European cities, and recently in San Francisco, Cal., rats have been sufficiently reduced in number to permit eradication of the plague. In San Francisco and its immediate vicinity, between May, 1907, and February, 1908, 77 deaths from plague occurred, and in the plague-prevention work carried on under supervision of the United States Marine-Hospital Service during the year beginning September 25, 1907, more than 300,000 rats have been captured, and it is estimated that nearly twice as many have been killed by poison.

Present methods of destroying rats are imperfect, and the expense is much greater than it should be. But even the crude methods of the past have saved a substantial amount to the country, and by cooperation and persistence the present improved means of destruction can be made to yield far better results than have yet been attained.

The amount spent in the United States in destroying rats is not known. In Stockholm, Sweden, from 1901–1906, inclusive, 639,515 rats were killed by the municipality at an expense in premiums of $8,570, or about 1⅓ cents per rat. Adding the expense of administration, the actual cost was less than 2 cents per rat. In the United States—as, for instance, in San Francisco—an extensive campaign against rats costs much more, yet it pays financially. But rats are such a menace to the public health that apart from pecuniary considerations they should be destroyed as completely as possible, and the war against them must be continuous to effect a permanent reduction in their numbers.

ESTIMATES OF LOSSES FROM RODENTS.

As in the case of carnivorous mammals, the following estimates are based on damages done in certain areas:

I.—*Losses due to European rats and house mice (including the brown rat, the house mouse, and the roof rat).*

Damage to grains while growing, in shock, stack, bin, crib, etc., up to December 1 each year (1 per cent of value)	$21,079,000
Damage to grains kept on the farm after December 1 for feed, seed, increase of price, etc. (1 per cent)	11,692,500
Damage to grains held in elevators, mills, warehouses, and in transportation on cars, ships, etc. (2½ per cent)	4,282,500
Damage to grain fed (largely in cities) to horses, hogs, poultry, etc., and entirely outside of farms and ranches	8,763,000
Damage to merchandise other than grains—dry goods, furs, meats, vegetables in stores and markets	10,000,000

Loss on young poultry, eggs, marketed (1 per cent of value, census of 1900)		$4,100,000
Fire losses due to rats and mice (one-fifteenth of $15,000,000)[a]		1,000,000
Total loss from European rats and house mice		$55,917,000

II.—Losses due to other rodents.

1. Pocket gophers:		
Damage to alfalfa	$4,000,000	
Damage to native hay	2,500,000	
Damage to clover and tame grass	3,000,000	
Damage to orchard and other trees	1,750,000	
Damage to gardens and crops not included above	575,000	
Damage to mowing machinery	800,000	
		$12,625,000
2. Ground squirrels (*citellus*), annual loss		10,000,000
3. Rabbits:		
Loss to nurseries	$1,200,000	
Loss to orchards	3,600,000	
Loss to forests, gardens, melons, etc	800,000	
Loss to pastures, stacks	400,000	
		6,000,000
4. Prairie dogs (*Cynomys*):		
Damage to pastures	1,500,000	
Damage to grain, forage, and other crops	1,000,000	
		2,500,000
5. Meadow mice:		
Damage to trees	1,800,000	
Damage to grain, alfalfa, hay, etc	1,250,000	
Damage to melons, gardens, etc	250,000	
		3,300,000
6. Woodchucks (damage to clover and hay and to haying machinery)		800,000
7. Cotton rats (*Sigmodon*)		800,000
8. Muskrats (damage to canals, embankments, etc.)		700,000
9. Other native rodents (wood rats, kangaroo rats, white-footed mice, and others)		1,250,000
Annual losses from native rodents		$37,975,000
Annual losses from European rats and mice		55,917,000
Total annual losses from rodents		$93,892,000
Annual cost of fighting rodent pests (traps, poisons, fumigators, bounties, labor)		3,000,000
Total		$96,892,000

---

[a] The underwriters place the losses due to defective wiring for electric lighting at $15,000,000 per annum, a large part of which they attribute to gnawing of the wires by rats and mice.

LOSSES TO LIVE STOCK BY DISEASE.

By V. H. Olmsted,
Chief of Bureau of Statistics, U. S. Department of Agriculture.

In compliance with the request of the commission, the following statements are submitted of the estimated percentages of loss to live stock from disease for a number of years, each year ending March 31. The figures have been reduced to five-year and three-year averages.

Estimated percentage of loss from disease for the year ending

HORSES.

[a] Four years.

DISEASES OF LIVE STOCK.

By A. D. Melvin,
Chief of Bureau of Animal Industry, U. S. Department of Agriculture.

The Bureau of Statistics of this department has submitted to the commission a statement showing the estimated losses of farm animals from disease and exposure for a number of years. The commission should consider in its report the losses from exposure as well as those from disease, as such losses are unquestionably large in the open range country during severe winters. It is believed that the numbers lost could be greatly reduced by leasing the range and allowing stock owners to fence it and to build sheds for the protection of the animals.

There is no doubt that by far the greater part of the losses of hogs from disease is due to hog cholera. For several years this bureau has been making investigations to determine the cause and develop a remedy, and recently a method of treatment has been worked out which is shown to be very effective in preventing the disease. The department is now endeavoring to induce the authorities of the various States to undertake the production of serum or vaccine according to the bureau's method and to supply this remedy to hog raisers in their respective States. If this plan can be carried out, especially in the large hog-raising States where cholera prevails, losses on account of this disease can unquestionably be greatly reduced.

The southern cattle tick (*Margaropus annulatus*) is the cause of heavy losses to the live-stock industry in the section where this parasite prevails. The infected area includes all or parts of the States of Virginia, North Carolina, South Carolina, Tennessee, Georgia, Florida, Alabama, Mississippi, Arkansas, Louisiana, Oklahoma, Texas, and California. This tick not only spreads the contagion of southern or Texas fever of cattle, but does considerable injury to the animals simply as a bloodsucking parasite. It is estimated that this tick is responsible for an annual loss of about $40,000,000 to the people of the infected country and that it also lowers the assets of the South by an additional $23,250,000.

The remedy for this condition is to exterminate the ticks, and this work has been in progress since the summer of 1906 by cooperation between the federal and state authorities. Within that time an area of over 63,000 square miles has been freed from the ticks and the practicability of their ultimate eradication has been demonstrated, although the undertaking will undoubtedly require several years and the expenditure of considerable money. It is believed, however, that the benefits will amply justify the expenditure.

Other sources of losses are the diseases known as scabies of sheep and cattle. Before this bureau undertook to control and eradicate these diseases, their presence in this country threatened serious injury to our export trade in live stock. While these diseases are not often directly fatal, they reduce the strength and vitality of the animals to such an extent that many die from exposure during severe weather.

There are also losses from reduction in flesh, and, in the case of sheep, decrease in wool production. For several years this bureau, in cooperation with State authorities, has been endeavoring to eradicate these diseases and good progress has been made. They have been entirely wiped out in several States and by continuing the work there is no question that they can be completely obliterated from the United States in the course of a few years.

Tuberculosis is perhaps the disease which causes the heaviest losses to the live-stock industry. During the fiscal year 1908 there were found affected with tuberculosis 0.96 per cent of the adult cattle and 2.05 per cent of the hogs examined in the federal meat-inspection service. Taking these figures in connection with reports of the tuberculin test on dairy cattle, it is estimated that more than 1 per cent of beef cattle, 2 per cent of hogs, and about 10 per cent of dairy cattle in the United States are affected with tuberculosis.

A careful study was recently made, followed by an estimate of the economic loss from this disease, and it was found that the loss probably exceeds $14,000,000 a year. Some of the items making up this amount are the loss on animals found tuberculous in the meat inspection, the depreciation in the value of the stock of farm animals remaining alive, the decrease in the milk yield of tuberculous cows, the impairment of breeding qualities, the increased cost of wholesome meat and dairy products, and injury to the trade in live animals and meats.

The remedy seems to be to eradicate tuberculosis from the farm animals of the country, and this is believed to be entirely practicable, although it will necessarily be a large and costly undertaking. The expense, however, will unquestionably be justified by the results. It has been clearly shown that hogs readily contract tuberculosis from cattle and that diseased cattle are the primary source of the infection in hogs. The main problem, therefore, is to eradicate the disease in cattle.

Live-stock owners should be aroused to the danger of having tuberculosis among their animals and should be educated as to the nature of the disease and the best methods of combating it. Valuable work in this direction may be done by the general and agricultural press and by official publications, also by lectures at public gatherings, farmers' institutes, etc.

The real work of eradicating tuberculosis, however, must be done by the federal and state governments in cooperation. There should be a systematic effort to determine to what extent and in what localities the disease exists, and the tuberculin test should be applied to cattle in such sections. The safest way of disposing of infected animals is to slaughter them. In order to reduce the financial loss to a minimum and at the same time guard against the sale of unwholesome meat, animals should be slaughtered at abattoirs under federal or other competent veterinary inspection. In this way a large proportion may be safely passed for food and made to yield its full meat value, while only those animals whose meat may be dangerous to health will be condemned.

An effective means of locating and eradicating tuberculosis of live stock would be to establish by state legislation a system of tagging cows sent to market for slaughter from suspected districts, so that if any were found tuberculous in the meat inspection, they could be traced back to the place of origin, thus locating centers of infection. The Bureau of Animal Industry is already cooperating with the authorities of some States by reporting on tuberculous animals, and the results so far have been very encouraging. To give the plan general application authorities should be empowered by law to require that shippers shall tag their cows in such a way that they may be identified and their origin determined.

Inspectors should be stationed at important points for the purpose of testing cattle for breeding and dairy purposes, and each State that is endeavoring to eradicate the disease should require that no cattle for breeding or dairy purposes shall be admitted from outside the State unless they have passed the tuberculin test. A good method of preventing the spread of tuberculosis among breeding stock would be the establishment by the State of one or more free herds of breeding cattle for the use of stock raisers in the State, or the State could certify to the health of free herds.

As the eradication of tuberculosis is largely a public health measure, it is not only reasonable that the State should compensate at least in part the persons whose cattle are slaughtered, but it is absolutely essential if the cooperation of cattle owners is to be secured.

The agricultural appropriation act for the current fiscal year authorizes the Secretary of Agriculture to investigate the prevalence and extent of tuberculosis among dairy cattle in the United States, and steps are being taken by this bureau to collect such information. Before any effective or extensive work of eradication can be undertaken, however, larger appropriations will be necessary.

A recent compilation and study of state laws on the subject show that very few States have adequate laws for the protection of live stock from contagious diseases and for the control and eradication of such diseases. Furthermore, very few States have made anything like adequate appropriations for the necessary expenses of effective work. An essential step toward any comprehensive work dealing with such diseases will be the enactment of proper legislation by the various States where this is lacking, and the appropriation of sufficient funds to carry on the work.

SHRINKAGE IN ANIMAL PRODUCTS DUE TO INJURIOUS INSECTS.

By C. L. Marlatt,
Bureau of Entomology, U. S. Department of Agriculture.

All domestic animals suffer seriously from parasitic and other insects, and above the reduction in the annual output of products is the heavy loss occasioned by certain insect pests to such stored and manufactured animal products as hides and furs, and stored animal food products. There is also the very serious check on production caused by the prevalence of certain insect-borne diseases of domestic animals. This last source of loss, however, is taken up elsewhere.

The value to the farmer of all animal products for the year 1907 is given in the report of the Secretary of the United States Department of Agriculture for that year as $2,678,000,000. This represents the products actually sold or consumed, and not the stock animals. Beef and dairy and all other domestic animals, including poultry, are subject to the attacks of biting and parasitic insects which operate as a very considerable check on fattening or on the yield of salable products. In the case of cattle the principal culprits are the ox warble and various biting flies and ticks. The damage chargeable to the ox warble was very carefully investigated several years ago by a western farm paper, and from the averages reported from the chief cattle States of the Mississippi Valley it was shown that 50 per cent of the cattle received in the Union Stock Yards at Chicago during the grubby season (from January to June) were infested and more or less injured by the presence of the larvæ of this insect. The depreciation in the value of hides and the lessened quantity and poorer quality of the beef indicated a total loss during the season of over $3,000,000. This loss applies only to the cattle coming to the Chicago market during the period mentioned, and is merely an indication of the much greater loss to range and farm stock throughout the country from this one pest. The loss for Great Britain from the warble has been estimated to vary from $10,000,000 to $35,000,000 per annum, and the total for the United States certainly can not fall below that for Great Britain.

The shrinkage or check to fattening or lessening of milk production, due to the annoyance from biting flies and other insect pests of cattle, represents a very considerable total every year; probably, in view of the greater prevalence of these pests, much more than is chargeable to the ox warble.

The loss to cattle production and values due to ticks (particularly the southern cattle tick responsible for Texas or splenetic fever) is enormous from the standpoint of the disease mentioned. This phase of the question, however, falls under a different section. Nevertheless, merely as parasites, ticks are a very serious pest in the South, seriously affecting the health and productive capacity of cattle.

Horses, sheep, and other farm animals, including poultry, are subject to the attacks of similar parasites and other insect enemies, and if all these be considered, including, for example, the buffalo gnats, often very destructive in the South, the many gadflies, botflies, the screw-worm fly, and such parasites as ticks and lice, a heavy percentage of loss must be reckoned. A 10 per cent annual loss has been assigned, certainly a conservative estimate, which represents a shrinkage for 1907 of $267,000,000 in value of animal products due to insect pests.

CONTROL OF INSECT ENEMIES OF LIVE STOCK.

A very large percentage of the loss to animal products from insect attack can be saved by the more general adoption of known remedies, but many of the problems are still under investigation. The tick problem is being actively investigated, and a rather simple method of rotation of pasturages seems to offer a practical means of control, and, under favorable conditions, of absolute extermination. A knowledge of the life history of biting flies and various internal parasites makes it possible to control these pests also in a considerable measure by limiting their breeding places and protecting cattle by the use of repellant washes or lotions. Such parasites as ticks and lice can also be controlled by intelligent quarantining.

THE PUBLIC RANGE.

By A. F. Potter,
United States Forest Service.

GENERAL DESCRIPTION.

There is no other natural resource of the country in which the people at large are more directly interested than in the use of the forage crop which grows upon the public lands. That there is a vast amount of land not at present susceptible of cultivation and so located that it can not be reclaimed by irrigation, which, for at least a long time to come, will be valuable only for grazing purposes, is a well-established fact.

The area of this land is probably not less than 300,000,000 acres, and includes parts of all the Western States. There is also a large area of partially wooded land, some of which has been included within the national forests, the principal agricultural value of which at present is for grazing live stock. In addition there is also land which can be reclaimed by irrigation, and a limited area upon which crops can be grown under favorable climatic conditions through dry farming, but which in the meantime is used only for grazing.

Most of this land has been occupied for many years by the stockmen of the West with their cattle, horses, sheep, and goats, and a large portion of the supply of beef, mutton, and wool furnished the markets of the United States has come from the herds and flocks grazed upon these public lands.

The use of the public lands, excepting such areas as have been withdrawn for national parks, national forests, military reservations, or other like public purposes, has always been free and unrestricted. This was a great advantage to the settlers on the frontier, and resulted in the establishment of many homes in localities where the lands were valuable only for grazing, but, on the other hand, it has resulted in serious abuse of the lands by persons who engaged in the live-stock business upon a speculative basis.

A very large proportion of the annual crop of grasses and forage plants can not be cut and kept for future use, but must be harvested by driving the live stock to the grazing grounds and allowing them to feed upon it. In this way the forage crop is converted into a marketable product, which adds very greatly to the general prosperity of the people and to the wealth of the nation.

The stockmen are thus enabled to make profitable use of the products of a very large area of foothills, plains, and desert lands which otherwise would go to waste. It is plain, then, that grazing is not only a source of prosperity under ordinary circumstances, as a close companion to agriculture, but is also one of the most important means of producing revenue from lands that are outside of the limits of profitable cultivation.

In the western range country stockmen have been among the earliest pioneers, and grazing has been the means of opening the way to other pursuits, because the herdsman with his cattle, horses, and sheep took possession of the frontier and opened up the way for tillers of the soil.

The evolution of the western range from grazing to cultivated land is brought about largely in the following manner: A portion of the range is fenced in order that the stock may be kept under control. The stockman prospects around for water, cleans out and improves the flow of springs, and finds places where water can be had by digging wells. Having succeeded in getting his pasture sufficiently watered for grazing purposes, he then gives his attention to seeing what can be done in the way of raising winter feed. Portions of the best land are set aside for cutting wild hay and experiments are made in raising cultivated forage crops. Where there is sufficient water for irrigation, the land is usually seeded with alfalfa, and immediately furnishes an increased amount of forage. The result is that it is soon found that the grazing capacity of the area has increased and the quality of the stock improved. This attracts the attention of others, and soon new divisions of the range are made. Settlers are attracted by the success of the stockmen in raising winter feed for their stock and try more varied farming. Thus the country changes to a more thickly settled and prosperous condition, and the successful establishment of homes is made possible upon the range lands.

On July 1, 1906, the total area of vacant public land was 418,358,752 acres. During the past ten years the average amount of public land disposed of annually has been about 18,000,000 acres. About two-thirds of the entries have been made under the homestead act. At this rate it will only be a few years until all of the land suitable for cultivation will have passed into private ownership. This does not mean that a less number of stock will be raised, but that a greater proportion of the animals will be fed upon the products of the cultivated lands, and that the need for an economic use of the remaining vacant lands will be increased proportionately, because in many instances the stock must be pastured on outside range during the growing period of the cultivated crop.

In reply to the questions asked in a circular sent out by the National Conservation Commission, 35 per cent of the stockmen heard from stated that they fed all of their stock upon the products of cultivated lands during the winter season, 35 per cent stated that they fed at least a portion of their stock during the winter, while only 30 per cent of the whole number reported that all their stock were pastured upon the open range during the entire year. This shows very plainly the close connection between grazing and agriculture, and indicates that beyond a doubt the practice of winter feeding is being adopted in many localities. The result will be to decrease the winter losses and place the live-stock industry on a much safer basis.

CAUSES OF DECREASE IN GRAZING VALUE.

At first, when the public lands were used only by the pioneers with their small bands of stock, there was an abundance of range for all and no one gave any thought to the future, but it was not long before men from the more thickly settled sections of country, where the ranges were becoming crowded, commenced to move westward in search of better opportunities, and gradually the range became more and more crowded.

The first effect of this was that the stock did not fatten as in former years, and consequently did not bring as good prices when marketed. Then, on account of the stock being in poorer flesh, the winter losses commenced to become greater and the percentage of natural increase smaller.

In localities where overstocking continued the grasses and forage plants were gradually trampled out until in many sections the grazing value of the lands was almost entirely destroyed. This was naturally followed by very serious losses of stock, particularly in seasons of drought.

The damage has not been done by any one kind of stock, but by all during different periods or in different localities. In the early eighties there was a great boom in the cattle business, and immense herds were driven to the ranges of the Southwest. It was only deemed necessary to secure a few watering places before turning loose unlimited numbers of stock upon the open range. There was no law to prevent overcrowding or to authorize any control whatever over the use of the lands. Under this condition of affairs it was not long until serious contentions arose, and out of it grew the notorious Lincoln County war in New Mexico and the Tonto Basin war in Arizona, both of which resulted in serious loss of life and property. While all of this was going on the carrying capacity of the range was gradually being diminished by grazing excessive numbers of stock, so that when in the early nineties there was a serious drought, the forage crop was entirely inadequate to support the number of animals, and a very large percentage died from starvation. At this same time the market prices for cattle and horses declined very greatly and many of the stockmen were compelled to close out their business through inability to make any profit or to meet their indebtedness. During this period the prices of sheep were also very low, but in the late nineties prices of wool and mutton began to improve, and many of those who had formerly raised cattle and horses engaged in the sheep business. The era of prosperity in sheep raising has continued up to the present time, and there is still a very great demand for the use of range by this kind of stock. The fact that sheep are herded has given their owners a great advantage on the open range, as herds are easily moved to localities where the feed is best or where there is available range.

There has been much complaint regarding the crowding in of sheep on ranges claimed by the cattlemen, and in many cases there has been serious conflict. In some localities the cattle owners through organized action have succeeded in keeping sheep off the ranges used by their cattle, but it is generally admitted that the increase in the number of sheep has compelled many of the smaller owners to discontinue raising cattle and to seek some other means of making a livelihood.

In such localities, and in many localities where no opposition was offered by the cattlemen, the number of sheep has increased until in the competition for range there has been very little regard for the interests of the public, and it has become a constant race from place to place in search of the most favorable feeding grounds.

The lack of control in the use of these lands has resulted in overgrazing and the ruin of vast areas of otherwise valuable range.

In response to a circular sent out by the Public Lands Commission in 1904, requesting information regarding the condition of the public-grazing lands, 80 per cent of the stockmen heard from reported the carrying capacity of the ranges they were using to have diminished, and 80 per cent of those making such report attributed the decrease to overstocking. Practically the same results have been obtained from a circular sent out this year by the National Conservation Commission, and, therefore, it is evidently a well-established fact that damage to the public-grazing lands is due almost entirely to the lack of any system or authority for its control.

METHODS FOR IMPROVEMENT OF GRAZING LANDS.

The most general method adopted by stockmen to control the use of public grazing lands has been through securing title to the watering places. If all of the water on a range could be secured, this has usually been recognized as giving the owner a right to the use of adjoining lands for grazing purposes, because in case of controversy he could fence up the water and thus prevent stock other than his own from using the outside lands.

However, the cases in which very large areas have been controlled in this way are exceptional, and as a rule it has only been successful as a means of securing the exclusive use of comparatively limited areas.

The most practicable method of controlling the grazing of stock is by fencing the lands into pastures. It has been found that wherever the lands were protected by fencing and overstocking stopped, the condition of the range at once improved and the amount of forage increased; better care is taken of the stock; losses from straying and death are lessened; a better grade of stock is raised, and in every way a better use of the land is obtained. Recent experiments made by the Forest Service in the use of fenced lands for the summer grazing of sheep have proven conclusively that they will carry 50 per cent more stock and at the same time produce better animals than are raised on the open range where the stock must be herded. Lambs raised in an experimental pasture in the State of Oregon weighed 10 pounds more than the same age and grade of lambs raised on the outside range.

In all of the Western States it is universally true that steers which are pastured on range controlled by fences outweigh steers from the open range and bring better prices on the market.

Experience in the management of grazing upon the national forests shows that upon ranges which were overgrazed prior to the enforcement of proper regulations a very large percentage of the forage is wasted through stock entering upon the range too early in the season, while the feed is immature. In the absence of any restriction there is always a race for feed in the early part of the season, each stockman trying to get upon the summer range first, in order to establish camps and hold the range. The serious damage caused by trampling is immediately stopped when the stock is kept off until the feed has a chance to get fairly started. In fixing the periods during which stock are allowed to graze within the forests, an endeavor is made to meet local conditions as nearly as possible and to allow the use of each district during the period when it is most needed and can be used to the best advantage.

By dividing the ranges into separate grazing districts and allowing the use of the lands by the kind of stock for which it is best adapted and during a proper grazing period, an increase of at least one-third has been made in the amount of forage utilized. Last year is was possible to increase the number of stock grazed upon 30 of the national forests on account of the improvement in the condition of the range which had been brought about by proper regulation.

In the answers which were received to the circular sent out by the Public Lands Commission in 1904, 15 per cent of those reporting improvement in the condition of their range attributed it to national forest regulation. Of the stockmen who, in response to the circular sent out by the National Conservation Commission this year, reported an increased amount of forage upon their ranges, 25 per cent credited the improvement to national forest regulation. This is a very satisfactory showing of the practical results which have been obtained and indicates that without doubt rapid advancement is being made in restoring the former grazing value of the lands.

Throughout the western range country the market for hay and other products of irrigated land depends very largely upon feeding live stock. In many places remote from transportation farming is only made profitable through raising live stock to consume the products of the farm. Cattle and sheep which are pastured in the mountains during the summer are driven to the fields in the fall after the crops have been harvested, and there fed during the winter.

As new areas are reclaimed and brought under cultivation by the Government and by private enterprise, the proper use of grazing lands in their vicinity becomes a matter of very great importance, because if the lands forming the watersheds of the streams are abused by overgrazing or improper grazing, then the water supply is diminished and, if the lands are not used for grazing, then the most profitable means of marketing the products of the land is removed.

The solution of this problem lies in the control of grazing upon the public lands and the enforcement of such regulations as are necessary to insure their permanent use for grazing purposes.

THE PUBLIC RANGE.

By A. D. Melvin,
Chief of Bureau of Animal Industry, U. S. Department of Agriculture.

From personal observation and from reports received from inspectors, there is no doubt that on the whole the carrying capacity of the public range has decreased.

This decrease is due to (1) the taking up of the public range by homesteaders, and (2) overstocking and misuse. The ranges have been overcrowded, especially at certain seasons and in the vicinity of watering places, and close grazing and trampling have in some places almost exterminated the native grass.

Measures should be taken to prevent overstocking and to protect the range so that the supply of grass may be renewed. There should be some system of government regulation of grazing on the public range. This could probably be best accomplished by leasing the range to stock owners and allowing them to fence the land. By this means the range would be brought under definite proprietorship, the lessees exercising control over the land and regulating the number of animals, which would encourage them to make improvements aiding in the conservation of both live stock and range. Such a plan would also assist in the control of contagious diseases and in the protection of live stock during the winter, two matters which are practically impossible of accomplishment on the open range under present conditions.

Reseeding the range where the natural grass has been destroyed would also be advantageous.

SWAMP AND OVERFLOW LANDS.

By Robert Follansbee,
United States Geological Survey.

INTRODUCTION.

The following report has been prepared in response to an inquiry from the National Conservation Commission regarding the area and ownership of the swamp lands of the United States, together with the cost and present status of reclaiming them.

In giving general estimates of swamp areas in the various States, the report of Prof. N. S. Shaler, published in the Tenth Annual Report of the United States Geological Survey, was used as a basis. The figures were modified, however, as further investigation showed them to be in error, or where subsequent reclamation work has changed their value.

The data regarding the present ownership have been derived mainly from the secretaries of state for the various States.

As the cost of reclaiming the swamp areas has varied widely, no attempt has been made to generalize, but instead typical examples in different sections of the country have been described as far as possible. These can be used as a basis for estimating the cost of future work. The data as presented were obtained for the most part from engineers and landowners directly interested, and should therefore be reliable within the limits noted elsewhere.

The data regarding the present status of the work have been compiled from various sources, mainly through the technical press and through correspondence.

ESTIMATE OF SWAMP AND OVERFLOW AREAS.

As noted in the introduction, the basis for the estimate of swamp areas in each State was Professor Shaler's report on swamps. His estimates have been modified either where a sufficiently large percentage of a State has been topographically mapped to show that such a change is necessary, or where information acquired by a personal visit to the State has shown them to be in error.

Wherever possible an attempt has been made to differentiate between permanent swamp and land periodically overflowed to such an extent as to render cultivation hazardous. But as Professor Shaler made no such distinction, it is not possible at present to separate the two types in the majority of cases. Also where the estimates were based on the topographic sheets they do not include the overflow lands, but it is believed there is not a great amount of land seriously overflowed in those States, with the possible exception of New Jersey and Oklahoma. Accompanying each estimate is a statement regarding its source, in order that some idea may be formed regarding its accuracy.

Swamp and overflow areas.

State.	Area (acres).	Authority.
Alabama	1,120,000	Shaler.
Arkansas	5,760,000	Do.
California	1,850,000	The area in Sacramento Valley was measured from a map of that section issued by the State in 1906, while the remainder of the area was obtained from the Land Office map.
Connecticut	37,700	State entirely mapped topographically, and estimate obtained by direct measurement.
Delaware	200,000	38 per cent of estimated swamp area mapped. Remainder uncertain.
Florida	18,560,000	Shaler.
Georgia	2,400,000	Do.
Illinois	2,688,000	This represents overflow areas along the streams as given by the State Geological Survey. It is estimated that 90 per cent of this area is either wholly or inadequately protected against floods, but if protection were afforded $150,000,000 would be added to the farm values of the State. The uplands are practically drained.
Indiana	1,000,000	This includes 600,000 acres of overflow land along the Wabash, West Fork of White, and Ohio rivers where levee protection is needed. Estimated from direct measurement of map compiled in field by writer. The remainder of the swamp area is found principally along Kankakee River, as most of the uplands are drained.
Iowa	800,000	Estimate based on the writer's knowledge of general conditions in the State. Areas found chiefly in north-central part and on Missouri slope. Drainage is progressing so rapidly that estimates must be revised frequently.
Kansas	160,000	Shaler.
Kentucky	224,000	Do.
Louisiana	9,600,000	Do.
Maine	240,000	The average swamp area per square mile for New York, New Hampshire, and Vermont was taken as the area per square mile for Maine.
Maryland	356,000	Swamp area practically mapped. Estimated from direct measurement.
Massachusetts	138,700	State entirely mapped topographically. Estimated from direct measurement.
Michigan	4,400,000	Shaler's estimate reduced somewhat to allow for land already drained.
Minnesota	4,500,000	Estimate based on Shaler. State has received 4,500,000 acres under swamp act. State drainage engineer estimates that there were 10,000,000 acres too wet for agriculture, of which 3,000,000 acres have been drained.
Mississippi	6,173,000	State Geological Survey.
Missouri	1,920,000	Shaler. Area chiefly in southeastern part of State.
Nebraska	256,000	Shaler.
New Hampshire	43,000	30 per cent of State mapped topographically. Assuming same ratio of fresh marsh to dry land mapped to hold true for entire State gives 37,400, or 43,000 acres of both fresh and salt marsh.
New Jersey	601,900	State entirely mapped. Estimated from direct measurement.
New York	576,000	81 per cent of swamp area mapped topographically.
North Carolina	2,400,000	Shaler.
North Dakota	226,000	Do.
Ohio	200,000	Based on writer's knowledge of general conditions.
Oklahoma	35,000	Includes Indian Territory. Swamp area practically mapped. Estimated from direct measurement.
Oregon	500,000	48 per cent of swamp area mapped. Remainder of area obtained from Land Office map.
Pennsylvania	96,000	52 per cent of swamp area mapped. Remainder of area somewhat uncertain.
Rhode Island	17,900	State entirely mapped. Estimated from direct measurement.
South Carolina	1,760,000	Shaler.
South Dakota	226,000	Do.
Tennessee	800,000	Do.
Texas	1,620,000	Do.
Vermont	70,000	Of area of State, 39 per cent mapped topographically. Estimate based on assumption that ratio of swamp to total area mapped applied to entire State.
Virginia	384,000	60 per cent of swamp area mapped. Remainder estimated from knowledge of general conditions.
Washington	75,000	52 per cent of swamp area mapped. Remainder of area uncertain.
West Virginia	2,500	State entirely mapped. Estimated from direct measurement.
Wisconsin	2,500,000	Shaler's estimate reduced somewhat to allow for land already drained.
Wyoming	25,000	Swamp area practically all mapped. Estimated from direct measurement. This is exclusive of Yellowstone National Park.
Total	74,541,700

OWNERSHIP.

Under the swamp act of 1850 practically all the public swamp lands have been donated to the States in which they are located, with the proviso that the funds derived from their sale shall be used to reclaim them. As a result, not more than 1,300,000 acres, approximately, remained as public lands June 30, 1907 (see Land Office circular on unappropriated lands). Such lands were donated only to the States existing in 1850, not to those thereafter admitted. These lands were located as follows:

	Acres.
Alabama	5,000
Arkansas	17,000
Florida	78,900
Louisiana	4,600
Minnesota (approximately)	1,200,000
Wisconsin	2,200
Total	1,307,700

This is approximately 1.7 per cent of the entire swamp area of the country.

The Commissioner of the Land Office for 1907 gave the following summary of swamp-land claims that had been approved:

Swamp-land claims approved and certified under various grants.

State.	Claims approved—total since dates of grant.	State.	Claims approved—total since dates of grant.
	Acres.		*Acres.*
Alabama	419,325.76	Minnesota	4,533,588.77
Arkansas	7,695,637.26	Mississippi	3,341,057.98
California	2,078,444.93	Missouri	4,498,573.28
Florida	20,458,866.46	Ohio	26,271.95
Illinois	1,497,028.35	Oregon	355,749.62
Indiana	1,266,075.75	Wisconsin	3,353,067.86
Iowa	942,180.67		
Louisiana	9,385,026.27	Total	65,582,503.50
Michigan	5,731,608.68		

The following table shows the amount of swamp lands still owned by the States, and also what disposal has been made of the remainder:

State ownership of swamp lands and method of disposing of remainder.

State.	Owned by State.	Disposal of remainder.
Alabama	0	State granted lands to trustees of Alabama insane hospitals.
Arkansas	200	
California	0	Practically all held in private ownership.
Connecticut [a]	0	Lands held in private ownership.
Florida	2,640,000	9,230,000 acres granted to private parties, canals, etc.; 8,230,000 acres granted to railroads.
Georgia	0	Practically all held in private ownership.
Illinois	0	State conveyed lands to counties, which sold them to individuals.
Indiana	0	Practically all held in private ownership.
Iowa	0	State conveyed lands to counties, which sold them to individuals.
Louisiana	0	State conveyed lands to various levee boards, which sold them to individuals.
Michigan	9,500	Remainder sold to individuals and proceeds of a part spent in reclamation work. The rest were disposed of under state homestead laws.
Minnesota	2,500,000	Remainder sold to individuals.
Mississippi	10,000	Remainder sold or donated to commissions for the improvement of certain rivers.
Missouri	0	Prior to 1869 some lands patented to individuals, but after that date the lands were conveyed to the counties.
New Jersey [a]	100	Remainder held in private ownership.
New York [a]	100	Do.
North Carolina [a]	230,000	These lands are owned by the state department of education. The remainder of the swamp lands are held in private ownership.
Ohio	0	Practically all held in private ownership.
Oregon	1,000	
South Carolina [a]	0	Lands granted to individuals.
Texas [a]	....	(No data.)
Virginia [a]	0	Practically all held in private ownership.
Wisconsin	50,000	2,000,000 acres sold for benefit of normal school fund. Remainder sold for benefit of general fund. The lands still owned by the State have recently been appropriated for a forest reserve.

[a] States did not receive lands under swamp act. In the States omitted from the above list the swamp areas are small and are chiefly owned by individuals.

COST AND RESULT OF RECLAIMING SWAMP LANDS.

The cost of reclaiming the swamp lands in the United States has varied so widely that no attempt will be made to reach general conclusions on the subject. Instead, typical examples in different parts of the country will be given in order that a basis may be formed for estimating the cost of future work.

With regard to the manner of reclamation, wet lands may be divided into two classes—(1) those requiring protection by levees from periodical overflows, with additional interior drainage; and (2) those that are wet the most of the year owing to defective natural drainage. This latter type is found not only along the rivers, but also on the uplands and frequently on divides. It comprises the greater part of the wet land and is, fortunately, capable of being reclaimed at less expense than the other type, and with less uncertainty regarding the success of the project. Usually all that is needed to drain swamps of this type is improvement of the natural drainage lines and the addition of artificial channels sufficiently large to take care of the run-off during the wet seasons.

The reclamation of wet lands of the overflow type involves a study of the rivers causing the overflow before protective measures can be undertaken intelligently. It is necessary to have records of flow extending over a series of years in order that the maximum discharge can be determined. When this is known, it is necessary to build levees of sufficient height and strength to withstand this maximum flow. As the building of the levees closes the natural drainage channels of the land protected, it is also necessary to construct artificial channels which lead either to reservoirs from which the run-off is pumped during high water or else to the lower end of the district, which is left open. Therefore it is easily seen that the reclamation of lands of this type involves greater expense and a higher order of engineering ability.

It is difficult to determine the actual cost of reclaiming the wet areas in the past, as much of the work done was inadequate to drain the lands properly and consequently further work was necessary to complete the drainage, and, as this work was done in a haphazard way, the total expense was greater than it should have been. Again, many of the drainage ditches have not been properly kept up, so it is difficult to say whether the cost given represents the complete reclamation of the land. The same thing is true of the levee systems. In the lower Mississippi Valley it is customary to leave the lower end of the districts open so that the interior drainage may have a gravity outlet, but in the upper valley, where the areas are much smaller, the districts are entirely closed, making pumping necessary during certain seasons, to properly care for the interior drainage and upland drainage adjacent. As many of the northern districts have either no pumping plants or inadequate ones, the result is that during periods of high water the protected land is more or less wet and so reclamation can not be considered complete. In the reclamation of both types of swamp, small yearly charges for maintenance are necessary in addition to the first cost.

With the foregoing limitations, examples of cost and result are given, which were obtained for the most part from engineers and landowners directly interested.

WET LANDS DUE TO DEFECTIVE NATURAL DRAINAGE.

Indiana.—Twenty-three thousand acres have been reclaimed in Morgan County at a cost of $4 per acre.

In 1900 a tract of 7,200 acres, adjacent to Kankakee River in La Porte County, was bought for $21 per acre. The cost of straightening the river channel and to tile draining brought the cost up to $55. The land is now selling for $100 and upward. As the Kankakee channel was not enlarged sufficiently to care for the maximum discharge, the land is overflowed in the spring and hence reclamation can not be considered complete.

Illinois.—In 1885, 35,000 acres of land in Mason and Tazewell counties were drained. Previous to drainage the land was worth $10 to $15 per acre, and eighteen months after the ditches were completed it was worth $50 to $60.

Three thousand five hundred acres have been drained in Champaign County at a cost of $5 per acre, with an increase in value of $75 for land fully reclaimed and $5 to $25 for partially reclaimed land.

In Whiteside County 28,000 acres have been drained at an average cost of $7 per acre, with an increase in value of $25 to $50.

In Bureau and Henry counties 33,000 acres have recently been reclaimed at a total cost of $420,000, or an average cost of $13 per acre. The 33,000 acres comprised land varying from permanent swamp to land wet only during rainy seasons. The swamp comprised one-fourth of the area and was assessed $10 per acre. This swamp land had no agricultural value, but was held at $25 for speculative purposes. The increase in value has been $30, exclusive of the cost of reclamation.

J. A. Harman, an Illinois engineer of wide experience in drainage, states:

> The cost of drainage of Illinois lands has varied greatly. On the flat prairie lands, where no water is to be cared for except that which falls directly upon the lands in the drainage district, from $3 to $5 per acre has been found sufficient to provide a drainage system of main ditches and $6 to $12 per acre additional for complete tile drainage. Where it is necessary to straighten streams of any considerable magnitude the cost ranges from $10 to $20.

Minnesota.—The state drainage engineer states that 3,000,000 acres have been drained in Minnesota at an average cost of $1.50 per acre, exclusive of tile drainage, which would cost $6 to $10 per acre additional. He cites an instance where land was drained in 1906, and in 1908 produced celery which gave a net return of $1,500 per acre.

Iowa.—Twenty-two thousand acres in Calhoun County were partially drained at a cost of $3 per acre, with the result of doubling the value of the land.

New York.—Thirty thousand acres in Conawango swamp were drained at a cost of $2.50 per acre. Previous to drainage the land was worth from $2 to $5, but after drainage was valued at $30 and upward.

South Carolina.—The sanitary and drainage commission of Charleston County reclaimed 75,000 acres of swamp in that county at a cost of approximately $1.50 per acre. The Secretary of the commission, Hon. James Cosgrove, states that the land was assessed at $2 per acre prior to drainage, but has now increased so in value that some of it is held at $250 per acre. Regarding the improvement to health, he quotes a letter from the A. C. Truxbury Lumber Company, as follows:

> We are in receipt of your letter of the 16th instant asking for our experience relative to the health of our employees, and in reply we wish to say that when we first decided to locate in Charleston and were looking for a site we were informed that the property adjoining Horlbeck's woods was considered very unhealthy, but we had faith in the work of the drainage commission and decided to erect our plant at that place. This section had always been unhealthy, so much so that it was impossible for the people to live in the vicinity. One of the first buildings which was erected was a large 20-room hotel, which was built in 1905 and has since been fully occupied by our employees, many of whom came from a different part of the country and were therefore unacclimated, but we have yet to hear of the first case of malaria at the hotel. This is also the case with all of our employees, and we are satisfied that this section is now as healthy as any in the country.

LANDS SUBJECT TO PERIODICAL OVERFLOW.

Cost for reclaiming lands of this type can be given only for the upper Mississippi Valley region, as investigations have not yet been made in the Southern States.

The result of leveeing the lands along the upper Mississippi has been to increase the value from $5 to $15 for unprotected lands to $70 to $100 for lands properly leveed and drained.

Reclaimed overflow lands on upper Mississippi River.

District.	Area.	Cost per acre.	Remarks.
	Acres.		
Drury	5,700	$18	Includes pumping plant.
Egyptian	11,000	18	No pumping plant.
Sny Island	110,000	20	No pumping plant needed.
South River	10,000	20	No pumping plant.

Along the Illinois River unprotected bottom land is worth $5 to $15, while fully reclaimed land sells for $100 and upward. Much of the land is leveed, but is not properly provided with an interior drainage system. Such land sells for $35 to $60.

Reclaimed overflow lands on Illinois River.

District.	Area.	Cost per acre.	Remarks.
	Acres.		
Big Swan	12,000	$18	No pumping plant.
Hillview	12,500	25	Includes pumping plant.
Nutwood	11,000	25	No pumping plant.
Partridge	3,000	30	Includes pumping plant.
Spring Lake	12,500	20	No pumping plant.

Mr. J. A. Harman, who was quoted previously, states:

> Along the Illinois River where it is necessary to construct levees which will average from 12 to 15 feet high, drainage ditches, and pumping plants, the cost varies from $20 per acre to $50 per acre for the leeves, main drainage system, and pumping plant. In no case so far has the cost been found prohibitive; in other words, these lands, which are subject to overflow and now have no productive value, but a speculative value of $5 to $25 per acre, can well afford a drainage tax of even as much as $50 per acre, because when drained they will have a productive value equal to the best land in the Mississippi Valley.

Indiana.—The O. P. D. levee opposite Newport protects 1,400 acres of land from the Wabash overflow at a cost of $20 per acre. There is no pumping plant.

In Sullivan County land that was worth $5 to $10 before leveeing is now worth $15 to $100 per acre.

COST OF FUTURE RECLAMATION.

As the reclamation of wet lands has been shown to involve inexpensive engineering work mainly, there is no reason to doubt that the greater part of the swamp and overflow lands in the country can be reclaimed at comparatively small cost per acre. Whether the character of the soil in all cases will warrant the expense can be determined only by further investigation, but the results already accomplished show that as a rule the wet lands are exceedingly fertile.

Whether the future cost of reclamation will be substantially the same as in the past, or whether it will be less, will depend largely upon the manner of doing the work. Especially is this true regarding the overflow lands. If these lands are reclaimed by the owners of different tracts acting independently of one another and reclaiming only comparatively small tracts at a time, with a possible result that protection to one section may make conditions worse in another, there is no reason to suppose that the final cost will be lessened except as methods and machinery are improved. But if the land along a river can be treated as a unit, the work can unquestionably be done more efficiently and cheaply.

In southwestern Indiana a preliminary report was made regarding the leveeing of 91,000 acres of Wabash River overflow, and it was estimated that the cost would be $8 per acre.

In Iowa drainage is being pushed very rapidly by means of drainage districts organized under state laws, whereby the land is assessed according to the benefits derived. In these districts the maximum assessments range from $3 to $11 per acre in the various districts.

In southeastern Missouri it is estimated that 500,000 acres of swamp and overflow land can be reclaimed at a cost of $10 per acre.

Mr. J. F. Le Baron, consulting civil engineer, after making preliminary surveys of the delta lands of Louisiana for the purpose of reclaiming them for rice culture, states (Trans. Am. Soc. Civ. Eng., vol. 54):

> If this land should be taken in single sections and it should be necessary to bring the water in a long flume and pump also, with a reservoir, the cost would be $16.50 per acre, while on the other hand in those locations where no pumping would be necessary, but the land could be flooded and drained by the action of the tide, the cost would be only $2.41 per acre. Each of these cases can occur on these lands.
>
> As to the income, the opinion is unanimous among all in that district with whom the writer has conversed that these reclaimed lands would rent easily and quickly for $5 per acre up to $14, with water supplied, paid in rice.
>
> These delta lands are so much richer than the prairie lands that, measured by their productiveness, they should easily bring twice as much, to say nothing of their immediate proximity to the metropolis of the State. There is no doubt they would be worth $200 to $300 per acre for truck farming when reclaimed, as some of these lands are only 3 miles from the center of the city of New Orleans, with a population of about 340,000.

PRESENT STATUS OF DRAINAGE.

While drainage work has been carried on for years in the upper Mississippi Valley, with the result that many hundred thousand acres in that section have been drained and are now among the richest farm lands, most of the other sections of the country have seriously considered the problem only within the past few years. The most feasible method of procedure has been the organizing of drainage districts by the landowners, under the state laws, with authority to raise funds by issuing bonds secured by the lands benefited. In this way the greater part of the land has been reclaimed.

Following is a brief account of the present status of drainage in each State:

Alabama.—Practically no work is being done in this State.

Arkansas.—Considerable work is being done in St. Francis Basin and in the southwestern part of the State.

California.—The most serious problem is the reclamation of the Sacramento Valley. In this section of the State, where the soil is extremely fertile, there are approximately 1,000,000 acres of swamp land, which may be increased in years of excessive high water. For years the landowners, assisted to some extent by the State, either through district organizations or by individual effort, have endeavored to levee the Sacramento River. These projects have been undertaken independently of one another, with the result that leveeing one section of the river, particularly in the lower region, has frequently made conditions worse in another section. It is estimated that vast sums, possibly reaching $20,000,000, have been spent chiefly by the landowners in river improvement and drainage work. Owing to the great amount of mining débris or detritus that is brought down by the Feather River into the Sacramento the river bed of the latter is constantly being built up, with the accompanying effect of lowering the levees.

In 1904 and 1907 the high water flooded several of the best levees of this district and did an immense amount of damage. The latter flood holds the record as to both height of water and damage done. The loss has been estimated at $5,000,000, most of which was on account of the damage to growing crops along the lower reaches of the San Joaquin and Sacramento rivers.

After the 1904 flood a state convention was called to consider the question, and a permanent organization, known as the "River Improvement and Drainage Association of California," was perfected. Through the efforts of this association many valuable data in regard to flood problems have been collected. A board was also organized consisting of three army engineers and the state engineer, which made a careful study of the situation, resulting in a federal appropriation for a detailed survey and report. This survey is being made at the present time by the army engineers. In addition to the above the State is cooperating with the United States Geological Survey in making detail topographic maps of the Sacramento Valley, and is also cooperating in the collection of run-off data. The Sacramento River being navigable, the Federal Government has done a large amount of dredging in an endeavor to maintain a navigable channel.

Florida.—The State has created a drainage district embracing most of the Everglades, and by imposing an annual tax of 5 cents per acre has created a fund with which to reclaim the land. At present there are two dredges at work cutting channels inland from the Atlantic Ocean. No other work of any size is being done in the State.

Georgia.—Attempts were made about 1894 to drain Okefinokee Swamp, but were abandoned before completion. No work is being done at present.

Drainage has been carried on actively for years, resulting in the drainage has been carried on actively for years, resulting in the drainage of practically all the upland marshes. The work remaining is chiefly protection against river overflow.

Illinois.—The last general assembly of Illinois made a small appropriation for the beginning of surveys and studies of the overflow lands of the State, for the purpose of acquiring a knowledge of the existing conditions and the methods by which the needed improvements may best be made. In accordance with this legislation, the State Geological Survey last year began the topographic mapping of portions of the Kaskaskia, Big Muddy, and Embarras rivers, in which it cooperated with the United States Geological Survey. As a result of this cooperation a topographic map on a scale of 2,000 feet to the inch, with a contour interval of 5 feet, is being made of important sections of these streams, the larger part of the work being carried on in the Kaskaskia River valley, the map of which is now practically completed from Shelbyville to the mouth of the river.

Indiana.—As in Illinois, drainage work has been carried on in Indiana for years, resulting in the drainage of the upland marshes. The work remaining is chiefly protection against the overflow of Wabash, White, and Kankakee rivers, but practically nothing is being done. Along the Kankakee River the problem has changed from that of draining marsh lands to protection against overflow.

Iowa.—Although drainage has not been carried on as long in Iowa as in Illinois and Indiana, it is being pushed very rapidly at present, with the result that the swamp lands are being rapidly drained.

Louisiana.—Beyond building levees along the Mississippi, little work has been done until recently. Now, however, a number of individuals have acquired large tracts of swamp land and are actively pushing the work of reclamation. The Manufacturers Record of June 18, 1908, describes approximately 320,000 acres that are being reclaimed.

Michigan.—In the Southern Peninsula drainage is being actively carried on, with the result that thousands of acres of the richest land have been reclaimed. The Northern Peninsula, however, is still heavily wooded, and until cleared there will be little drainage work undertaken.

Minnesota.—The State owns approximately 2,500,000 acres of wet land, for the drainage of which the legislature has appropriated $50,000 per year, and created a drainage commission, consisting of the governor, state auditor, and secretary of state. Up to 1906 the State had spent $317,000. The owners of the remainder of the swamps are actively engaged in draining them, with the result that the state drainage engineer estimates that all the lands will be drained in fifteen years at the present rate of progress. Provision was made by the Nelson Act of 1889 for the settlement by homesteaders of the ceded Chippewa lands of northern Minnesota, comprising an area of over 5,000 square miles. The settlement of these lands ceased immediately after the occupation of the high portions, as the remainder was almost entirely swamp. Congress on June 21, 1906, authorized the Secretary of the Interior to make a drainage survey of the lands in this area which remained unsold and which were wet or swampy in character, with a view to determining what portion thereof might be profitably and economically reclaimed by drainage. This survey has just been completed under the direction of the Director of the United States Geological Survey, and the results will be reported to Congress during the winter. The report for the Mud Lake district within this area has been completed and is included in Document 607, House of Representatives, Fifty-ninth Congress, second session, and is in sufficient detail to permit immediate construction work should Congress consider this step advisable.

Mississippi.—The levee along the Mississippi River is now practically completed. It is estimated that within the next two years this great work will be accomplished and will prevent in the future all overflows of the Yazoo Delta from this source. There is great activity in various sections of the State looking to the drainage of the very fertile delta lands. An act was passed by the legislature of the State on March 2, 1908, creating the Tallahatchie drainage district, incorporating the Tallahatchie drainage commission, and authorizing the governor to appoint the members thereof. This commission was given the right of eminent domain and empowered to issue bonds, levy and collect taxes for drainage construction, and enter into cooperation with the United States Government for making topographic surveys and maps of said district. Cooperation between the governor of Mississippi, the Tallahatchie drainage commission, and the United States Geological Survey was entered into on June 15, 1908, for the topographic mapping of this area on the scale of 2,000 feet to the inch, with a contour interval of 5 feet. Since that time active work has been in progress and about 40 per cent of the estimated area of the district (1,800 square miles) has been completed.

Missouri.—A drainage district has been formed to reclaim 500,000 acres of land in the southeastern part of the State. Preliminary surveys have been made, and from these it is estimated that the cost will be $5,000,000. Considerable work is being done by landowners to protect lands from overflow along the Grand, Marais des Cygnes, Tarkio, and Chariton rivers.

Nebraska.—Considerable work is being done to protect the bottom lands of the Missouri from the overflow of the tributaries coming from the bluffs.

New Jersey.—The State has made appropriations ($23,000 in 1907) for ditching the salt marshes for the purpose of exterminating the mosquitoes. Although the work enables marsh hay to be grown, diking against high tides is necessary for complete reclamation.

North Carolina.—Very little work has been done, but the State recently turned over to the control of its Geological Survey two swamps aggregating 55,000 acres. This was done for the purpose of studying the feasibility of draining them. A state drainage convention was held September 9 and 10, 1908, to stir up interest in drainage and to devise means for prosecuting the work.

North Dakota.—Preliminary surveys were made several years ago to protect thousands of acres from Red River, but no actual construction work has been done.

Oregon.—In connection with an irrigation project a considerable portion of the swamps in the vicinity of Klamath Lakes is being drained by the United States Reclamation Service.

South Carolina.—The only considerable work is the continuation of the work of the sanitary and drainage commission of Charleston County in reclaiming the swamps of that county. This commission was organized under the state laws.

South Dakota.—Several drainage districts have been organized to drain the lands in the Missouri bottoms.

Texas.—A number of drainage districts have been organized to reclaim land in the southeastern part of the State.

Virginia.—At present nothing is being done to reclaim the largest swamp area in the State—the Dismal Swamp. Capt. John G. Wallace, who has spent his life in that region, states that no steps will be taken by the owners until the route of the proposed Chesapeake and Albemarle canal is decided upon, as that will influence the drainage problem.

Wisconsin.—Drainage is being pushed fairly actively, with the result that thousands of acres have already been reclaimed.

Nothing is being done in the States omitted from the foregoing list. In most of them the swamp areas are small and scattered.

WORK OF THE UNITED STATES GEOLOGICAL SURVEY.

By two branches of the Geological Survey work is being done which has an important bearing on the reclamation of swamp lands; these are the topographic and the water-resources branches.

The work of the topographic branch consists in making a topographic map of the entire country, about 35 per cent of which has been completed. It includes a considerable portion of the swamp and overflow areas, and in addition to the actual swamp lands the higher land adjacent has been mapped, a work which is essential to a thorough understanding of the drainage problem. In connection with the surveys for mapping purposes, level lines are run giving accurate elevations, and thus much information necessary for making drainage plans is obtained.

In the water-resources branch the work consists chiefly in maintaining records of flow of the principal streams, and in this way data are being collected regarding the flow of streams that are either outlets for swamps or that overflow their bottom lands. While the information gathered is of importance in connection with the reclamation of lands of both types, it is especially valuable in the matter of leveeing overflowed lands, where the maximum discharge must be known if the reclamation is to be complete.

Besides the above work, data are being compiled relating to size and location of various swamp areas, in order that a map of each State, showing swamp conditions, may be prepared. Methods and cost of reclamation are also being studied, in order that the cost of future work of the same kind may be closely estimated.

SWAMP AND OVERFLOW LANDS.

By Dr. A. C. True,
Director of Office of Experiment Stations, U. S. Department of Agriculture.

The term "swamp and overflow lands," as commonly used, refers to lands which in their natural state are unfit for cultivation by reason of their swampy and overflowed condition. The term, as used by agriculturists, has reference to lands which can not be profitably cultivated without draining. The total area of swamp and overflow land in the United States was ascertained by a recent investigation made by the Department of Agriculture as 79,005,023 acres. These lands are classified as follows:

	Acres.
Permanent swamp land which is never fit for profitable cultivation or grazing	52,665,020
Lands which afford pasturage for stock, usually termed "wet grazing land"	6,826,019
Lands which in their natural condition are subject to periodical overflow by streams, but which at other times produce valuable crops, and called "periodically overflowed land"	14,747,805
Lands which may be profitably cultivated during seasons of light rainfall, but in other seasons are too wet for cultivation, and designated as "periodically swampy land"	4,766,179
Total	79,005,023

In addition to this area there are 100,000 acres of land in the arid west, once irrigated, which have been abandoned because of swampy or wet condition, and an additional 661,000 acres which are only partially productive because of their wet condition.

By the act of Congress of 1850, and subsequent acts, all federal swamp and overflowed lands were granted to the States in which they were located. With the exception of 3,200,000 acres of ceded Indian lands in the State of Minnesota and an undetermined amount in the State of Florida not yet claimed by the State, all the swamp and overflowed lands are owned by individuals, companies, or States.

The term "reclaimed land" has no exact meaning, but commonly refers to wet lands which have been wholly or partially improved by draining. Lands are frequently said to be reclaimed when relieved of water only sufficiently for pasturing purposes. By many landowners the term is applied only to lands which have been drained sufficiently to produce all kinds of cultivated crops which are adapted to the climate and soil. It is estimated that 15,889,000 acres have been reclaimed for profitable farming purposes, a large part of which lies in the Mississippi River valley.

Swamp lands lying in the prairie regions have been sufficiently drained for use as lowland pastures at a cost of $2 to $4 an acre. When the same land is drained for the production of cultivated crops the cost amounts to $15 to $20 an acre, and sometimes as high as $30 an acre.

Timbered swamp land costs 25 per cent more to drain than prairie land, and $20 an acre more to clear it of stumps and prepare it for cropping.

The 15,889,000 acres which have been converted from permanent swamp into arable land are now well-improved farms which produce a maximum yield of crops. Many of such farms are worth not less than $100 an acre, the value of the land without surface improvements being $75 an acre.

A conservative estimate of the increased value of farm lands due alone to draining is $320,000,000 over and above the cost of the operations.

Of the estimated 79,000,000 acres of swamp and overflowed land it is probable that only about 60,000,000 acres can be reclaimed and made profitable for agriculture under the present condition of labor and the demand for products. The production of lands already under cultivation is being increased. The productive value of many of the unreclaimed swamp lands, when drained, is problematical.

The cost of the construction of the larger works of drainage is decreasing, by reason of improved machines and methods of excavating large channels. The cost of such work has decreased one-half during the last fifteen years. The expense of developing the land, after the main drainage has been provided, is probably 20 per cent higher than it was fifteen years ago. A safe estimate for draining 60,000,000 acres sufficiently for good farming land is $20 an acre.

Our country could support 600,000 more families upon farms thus drained, and as many more who would be engaged in other occupations in the towns and villages which would follow the development of the land.

TENURE OF FARM LANDS.

By Prof. **Le Grand Powers**,
United States Census Bureau.

For the last half century at least there has been a decided tendency toward smaller individual farm holdings. The data upon which this statement is based were obtained largely from the reports of the United States Census Bureau. These reports for the various census years are on slightly different bases, and a statement of the differences may as well precede an exhibit of the facts to be gleaned from the reports of that office.

The first statistics of American farm holdings that can be compared with those of the present day were collected in 1850. In that year the United States census ascertained the number of farms and the total number of acres in farms, and thus obtained the data for determining the average size of farms. It did not, however, ascertain how many of these farms were cultivated by owners and how many by tenants, the number of separate individuals who owned farm lands, or the total number of farms of any specified area. The information collected by the census in 1860 and 1870 was identical in character with that secured in 1850.

In 1880 the census began to collect information relating to farm tenure, or the number of farms cultivated by owners and tenants, and tabulated the data so as to show the number of farms of each of a number of specified areas. The information collected and the tabulation employed in the census of 1880 have been made use of in each succeeding census, including that of 1900. In addition, the census of 1900 secured and tabulated certain information relating to the ownership of tenant farms. The data thus collected for six decennial years furnish a fair basis of ascertaining the trend in the greatest of American industries with respect to the average size of the holdings occupied and cultivated by a farm owner or farm tenant and the average size of holdings of the persons owning farm land. The facts disclosed by these census data are here discussed under a number of distinct heads, the first to be considered being that of the average holdings of those who occupy and cultivate farm land. The facts relating to this subject are reviewed under the title which follows:

DECREASED HOLDINGS OF FARMERS OR FARM CULTIVATORS.

For the purpose of summarizing these data the census arranged the States and Territories of continental United States into five divisions, to which it gave the names of North Atlantic, South Atlantic, North Central, South Central, and Western.

The census data showed that the past changes and present conditions with respect to holdings in the States which were fairly settled before 1850 were different from those changes which have taken place or the conditions which exist in the great majority of States settled in later years. To bring out the difference here noted, the North Central and South Central States were divided into two groups, here referred to as "old" and "new." The "old" North Central States are Ohio, Indiana, Illinois, Iowa, Missouri, and Michigan; the "new" North Central States—Wisconsin, Minnesota, Kansas, Nebraska, North Dakota, and South Dakota. The new South Central are Texas and Oklahoma. The data for the latter were given in the census reports under the title of Oklahoma and Indian Territory. All the other States of the South Central division are here referred to as the old South Central. The States and Territories included in the North Atlantic, South Atlantic, and old North Central and old South Central divisions are here referred to as the older group and all other States as the newer group. The data collected by the census showed that in the older group there has been a marked and almost unbroken tendency toward smaller holding by individual farm cultivators from 1850 to 1900. Every State within this group had a smaller average area of farm holdings in each census year than it had ten years previous; but combining the data of these individual States into groups, the old North Central had an average greater in 1890 than in 1880, due to the different combination of the data for the individual States. In the newer group there was a marked tendency from 1850 to 1870 toward smaller holdings, but since that time a tendency in the opposite direction. The average size of the farm holdings of individual cultivators was given for each of the two groups and the seven divisions of States here mentioned for each of the census years from 1850 to 1900:

TABLE 1.—*Average acreage of holdings of farm cultivators, 1850 to 1900.*

Groups and divisions.	1900.	1890.	1880.	1870.	1860.	1850.
United States	147.0	136.5	133.7	153.3	199.2	202.6
Older States	103.4	117.0	124.0	147.7	190.9	194.6
North Atlantic	97.5	95.3	97.7	104.3	108.1	112.6
South Atlantic	109.1	133.6	157.4	241.1	352.8	376.4
Old North Central	112.2	115.4	114.3	122.3	141.3	143.0
Old South Central	91.3	121.7	136.4	179.9	286.0	250.8
Newer States	297.7	205.8	179.6	195.7	286.6	488.4
New North Central	213.2	171.1	143.3	130.1	129.4	147.8
New South Central	324.4	223.7	208.4	301.0	590.9	942.5
Western	393.5	324.1	312.9	336.4	366.9	694.9

FARMS OF SPECIFIED AREA.

Mention has been made of the fact that since 1880 the census has so tabulated its data relating to farms and farm area as to disclose the number of farms of specified area. The data thus secured were given for the United States and for the two general groups mentioned in the following table:

TABLE 2.—*Number of farms of specified area, 1880 to 1900.*

Area in acres.	United States.			Older States.			Newer States.		
	1900.	1890.	1880.	1900.	1890.	1880.	1900.	1890.	1880.
Under 10	233,697	150,194	139,241	198,058	135,979	127,219	35,639	14,215	12,022
10 and under 20	406,641	265,550	254,749	352,193	237,525	227,067	54,448	28,025	27,682
20 and under 50	1,257,496	902,777	781,574	1,047,060	778,134	684,394	210,436	124,643	97,180
50 and under 100	1,366,038	1,121,485	1,032,810	1,096,239	928,477	874,573	269,799	193,008	158,237
100 and under 500	2,390,282	2,008,694	1,695,983	1,590,818	1,408,227	1,309,602	799,464	600,467	386,381
500 and under 1,000	102,526	94,395	75,972	44,599	64,674	61,197	57,927	29,721	14,775
Over 1,000	47,160	31,546	28,578	13,094	17,541	20,857	34,066	14,005	7,721

In the compilation of the tables no account was taken of a certain small number of farms reported in 1900 which contained less than 3 acres. They were omitted as being of a character not included in the earlier census reports and their inclusion would make the figures not strictly comparable for the several years.

In the older group there was a continued and unbroken increase in the number of farms containing less than 500 acres and a corresponding decrease in the number of farms of greater area. The increase in the average size of farms shown for this group in Table 1 was, therefore, caused principally by a breaking up of the larger farms of the earlier years and the substitution of smaller ones in the later. At the time of their settlement there was the same tendency in the older States to acquire large holdings that is to be witnessed in the newer States at the present time. Then, as now, men who obtained land for nothing or for a nominal consideration secured all they could without regard to the area that could profitably be utilized by them for agricultural purposes. Later the holdings thus obtained must be adjusted to the area that can most economically be cultivated by the individual farmer. In the older group this has tended for fifty years to be of smaller and smaller area. Time alone can tell whether such will be the tendency in the newer group. All available information leads, however, to the conclusion that the census of 1910 will disclose a marked tendency in the newer groups of the same character as the one shown in Table 2 for the older group.

OWNERSHIP OF AGRICULTURAL LAND.

The Twelfth Census was the first to collect data relating to the ownership of rented farm land, although the information secured was not sufficiently complete to establish definitely the total number of individuals owning farm land and thus the average size of the holdings of such owners; yet it suffices for the student of the subject to establish that number and that area within narrow limits for correctness. Well-known facts relating to agricultural lands and agricultural holdings in 1850 enable the student to secure the same data for the date mentioned within narrow limits of accuracy. The comparison of the available data throws much light upon the question: Has the title to American farm land tended in the last fifty years to pass to a fewer or larger relative number of individual owners?

In 1848 Gov. John Young, in his message to the New York legislature treating of the legislation needed to enforce the provisions of the third constitution of that State, adopted in 1846, forbidding the longer continuance of the feudal tenure of agricultural land, estimated that the manorial holdings in New York aggregated 1,800,000 acres, and that 260,000 people were residing on such holdings. These 1,800,000 acres were owned by relatively few proprietors. The number of separate farms on this area could not have been less than 30,000 and may have exceeded 40,000, provided the estimates of Governor Young concerning the population residing upon the same were correct; and the number of farm owners in the State was less than the number of farms by not less than 30,000, and it may have been less by over 40,000. The foregoing figures assume that the great number of tenant farms in New York in 1850 other than those held in feudal or manorial tenure were occupied by the children of their owners. Making the same exception for the older States previously mentioned, and combining the statement of Governor Young with the census returns of the number of individual farms, the conclusion is reached that the number of persons residing in the older States and owning farm land in 1850 was not more than 1,370,000, and it may not have been over 1,350,000; and the area owned by each averaged not less than 200, and that average may have been as great as 203.2 acres. In the newer States in 1850 the census reported only 39,244 farms, with an average area of 488.4 acres. The number of persons owning tenant-operated farms was doubtless nearly as great, if not quite the same, as that of such farms; and hence the average area of land held by an individual owner was not less than 488 acres. Taking the country as a whole, and combining the data reviewed for the two great groups, we reach the conclusion that in 1850 the number of persons owning farm land in the United States numbered not less than 1,390,000, and may have reached 1,410,000, with an average in the one case of 211.2 acres and in the other of 208.3 acres.

Of the 5,737,372 farms in continental United States in 1900, 2,024,964 were operated by tenants and 3,712,408 by their owners. It was further ascertained that 1,257,716 different persons owned 1,934,346 tenant farms whose owners were ascertained. The number of tenant farms, the names and residences of whose owners were not ascertained, was 90,618. For the farms whose owners were ascertained, there was one owner for every 1.54 farms. Allowing the same relative number of owners for the farms with ownership not reported, the tenant farms of the United States in 1900 were owned by 1,316,516 separate persons. Of these persons a limited number were operating owned farms, and thus included in the 3,712,408 persons operating farms of their own. The number of these persons was not ascertained. It probably was not less than 10 per cent and was with equal probability not more than 20 per cent of the number of persons owning leased farm land, or in other words, was not less than 130,000 and may have reached 275,000. Allowing these numbers, we find that the number of different persons owning farm land in 1900 was not less than 4,563,000 and may have equaled 4,893,000. The average holdings of the individual owners, therefore, was not less than 171.2 nor more than 176.5 acres.

The foregoing figures may be compared with the corresponding totals for the United States in 1850 when the average owned acreage of farm land was not less than 208.3 and may have equaled 211.2 acres. In spite of the enormous holdings of a few owners in the newer States, some of which holdings are over 1,000,000 acres, the general movement of agricultural land is not only to be cultivated in smaller holdings but is to be owned in smaller parcels.

The data secured do not admit of satisfactory analyses along the same lines for the several groups of States, owing to the fact that some land located in one State or group of States is owned in other States. Allowing somewhat for this fact, the data obtained lead to the conclusion that in 1900 the 4,317,243 farms of the older group of States were owned by not less than 3,550,000 and by not to exceed 3,700,000 persons. This would give the average area owned by an individual of not less than 120 nor more than 125 acres, as compared with the average in 1850 of 200 to 203.2 acres. The area of land owned by an individual capitalist has, therefore, decreased in these older States almost as much as has the area tilled by the average farmer.

CAUSES OF TENDENCY TO DECREASE FARM HOLDINGS.

The principal tendency to decrease farm holdings is social in its origin. The abolition of slavery changed the status of a great army of farm toilers; men who once were slaves, if retained on the farm, must be owners, tenants, or hired laborers. Since emancipation there has been a social movement among former slaves which has elevated a great portion of them and of their descendants, and they have become farm tenants. The small capital and lack of skill on the part of these former slaves, as well as the absence of any large amount of possible hired labor, makes these former slaves occupiers of small farms, and their rise to tenancy becomes a most potent factor toward lessening average farm holdings.

A change in the average status of farm labor in the old Northern States has the same influence. The possibility for poor men who leave the East and go West to become owners of farms carved out of the Government land has, with the passage of years, made an increasing number of adult male farm workers unwilling longer to toil for wages on the farm. If they can not secure a farm in the Northeast as a tenant, they will leave that section of the country and drift to the West. Hired labor can not be easily secured by those who have passed the age at which they wish to engage in hard farm labor. As a result, tenant labor displaced hired labor in the North as it displaced slave labor in the South, and with the decrease of hired and slave labor and an increase of tenant labor, the number of independent farms and farmers increases and thus forces a change in the size of farm holdings for the cultivation of the soil. Within narrow limits, the factors which determine the amount of land that the average farmer cultivates under his immediate management also determine the area of the tract which the average individual capitalist will acquire and continue to own.

Whatever may have been the effect upon the production of the soil of this decrease in the size of farms cultivated by the average owner, there can be no question that the decrease and the consequent enormous increase, actual and relative, in the number of farm owners is of tremendous social significance. It measures the enormous increase of independence among the farmers and a corresponding decrease in the number of farm dependents, as can be seen by an analysis of the constituent parts of American farm population which follows.

FARM TENURE AND THE STATUS OF FARM LABOR.

The census statistics of occupations for the later census years have been taken and compiled on a basis quite different from that of 1850. As a result, no comparison can be made between the status of agricultural labor in 1850 and 1900 without making use of some estimates for the earlier year. The writer estimates on the basis of the census data for 1850 and later years that the males employed in agricultural labor on American farms in 1850 could not have been less than 3,500,-000. At that time the farms numbered 1,449,073, some of which were operated by women, as has been the case in all subsequent years. Of the 1,449,073 farms, not less than 40,000 in New York alone were operated by tenants, according to the data contained in Governor Young's message in 1848, and the number may have exceeded 50,000. The total number of tenant-operated farms in the United States could not have been less than 100,000; and of 1,000 farm owners and tenants, and males over 15 years old other than owners and tenants, working on American farms, approximately 376 were farm owners, 28 farm tenants, 373 were wage-earners and children of farm parents, and 223 slaves.

In 1900 the males 15 years of age and over working for wages in continental United States numbered 8,549,739. The farms tilled in part or wholly by their owners were 3,712,408, and those tilled wholly by tenants were 2,024,964. For every 1,000 farm owners, tenants, and male workers other than owners and tenants over 15 years of age engaged on farms, there were 417 farm owners, 227 farm tenants, and 256 others, of whom substantially one-half worked for wages or for their parents.

The relative number of farm owners was greater in 1900 than in 1850; the relative number of tenants was much greater in the later than in the earlier year, and has shown a tendency to uninterrupted increase, while that of the lowest form of farm labor has shown a most marked tendency to decrease in relative importance. With slight changes in the relative condition of farm work, there has been a tendency in fifty years to substitute tenant labor for slave and hired labor, and this tendency has been a most important factor in affecting farm tenure, the average size of farm land cultivated by the individual farmer, and indirectly in increasing the relative number of persons owning farm land and in decreasing the size of land owned by the average individual landlord.

FISHERIES OF THE UNITED STATES.

By Dr. Hugh M. Smith,
Of the Bureau of Fisheries, Department of Commerce and Labor.

The following table gives the principal annual statistics regarding the fisheries of the United States:

Items.	Total.	
	Number.	Value.
Persons employed	219,534	....
Vessels fishing	4,899	$9,425,723
Tonnage	97,188	....
Outfit	....	3,443,724
Vessels transporting	2,038	4,687,891
Tonnage	92,402	....
Outfit	....	371,465
Boats	83,800	6,040,438
Seines	5,652	893,083
Gill nets	253,228	2,449,734
Trammel nets	1,811	85,690
Pound nets, trap nets, and weirs	12,912	3,602,408
Fyke nets	60,203	360,169
Stop nets	359	22,202
Beam trawls	75	2,267
Paranzella nets	32	5,800
Wheels and slides	90	109,255
Lines	....	416,494
Eel pots	29,956	27,413
Lobster pots	198,130	221,561
Dredges, tongs, rakes, and hoes	....	400,101
Crab dredges and scrapes	....	11,791
Crowfoot grapples, rakes, etc.	....	13,683
Sponge apparatus	....	6,663
Other apparatus	....	94,435
Shore and accessory property	....	35,853,934
Cash capital	....	25,648,914
Total	....	94,254,839

The following table shows the annual amounts and value of the products of the fisheries by species:

Products.	Pounds.	Value.
Alewives	52,061.580	$473,811
Barracudas	2,194,717	53,073
Black bass	1,939,571	150,471
Bluefish	16,575,661	781,802
Bonito	1,231,094	44,893
Buffalo fish	14,534,141	340,397
Butterfish	4,184,363	138,761
Catfish	12,718,003	531,529
Cod	85,193,618	2,295,068
Crappie and strawberry bass	1,397,306	61,188
Croaker	7,032,243	142,076
Cusk	9,079,866	139,964

Products.	Pounds.	Value.
Drum, fresh-water	3,512,881	87,94[illegible]
Drum, salt-water	4,063,230	109,0[illegible]
Eels	3,815,916	223,8[illegible]
Flounders	18,094,317	445,6[illegible]
German carp	18,942,763	442,2[illegible]
Haddock	77,065,441	1,258,70[illegible]
Hake	35,928,627	419,38[illegible]
Halibut	15,806,776	590,90[illegible]
Herring	87,846,283	728,2[illegible]
Herring, lake	32,177,689	816,04[illegible]
Mackerel	16,458,604	1,110,4[illegible]
Menhaden	562,427,449	1,452,0[illegible]
Mullet	[illegible]1,747,130	709,4[illegible]
Paddlefish	1,421,086	45,9[illegible]
Paddlefish caviar	11,171	7,0[illegible]
Perch, white	2,674,763	160,87[illegible]
Perch, yellow	7,080,770	182,27[illegible]
Pike perch	10,899,604	457,97[illegible]
Pike and pickerel	1,451,270	79,72[illegible]
Pollock	29,033,093	305,4[illegible]
Pompano	910,155	61,4[illegible]
Rockfish	1,896,467	63,4[illegible]
Salmon	267,601,561	12,615,74[illegible]
Scup	9,216,731	250,2[illegible]
Sea bass	4,282,313	183,21[illegible]
Shad	28,563,385	1,702,37[illegible]
Sheepshead	2,634,046	68,0[illegible]
Silver hake	5,549,935	37,9[illegible]
Smelts	3,414,662	152,4[illegible]
Snapper, red	13,763,653	418,3[illegible]
Snapper, other	401,349	11,41[illegible]
Spanish mackerel	3,673,846	171,97[illegible]
Spot	2,023,476	65,7[illegible]
Squeteague	44,783,504	1,265,5[illegible]
Striped bass	4,171,758	352,04[illegible]
Sturgeon	3,146,398	149,54[illegible]
Sturgeon caviar	114,814	83,40[illegible]
Suckers	9,538,639	196,304
Sunfish	2,088,519	52,00[illegible]
Swordfish	3,311,369	205,5[illegible]
Tautog	847,756	28,2[illegible]
Trout	20,158,954	1,081,117
Whitefish	7,728,761	350,18[illegible]
Whiting and kingfish	1,178,650	56,107
Other fish	13,651,988	313,82[illegible]
Clams, hard	9,064,852	1,385,44[illegible]
Clams, soft and other	8,438,510	574,00[illegible]
Mussels	1,580,065	8,4[illegible]
Mussel shells	51,856,430	530,0[illegible]
Oysters	217,787,610	18,449,104
Oyster and other shells	19,983,845	20,70[illegible]
Scallops	1,586,151	297,6[illegible]

Crawfish	447,664	20,90[illegible]
Shrimp and prawn	17,689,539	393,6[illegible]
Shrimp shells	950,000	4,300
Sponges	346,889	364,422
Terrapin and turtle	1,4[illegible]9,314	114,494
Oil, fish	745,162	20,047
Oil, whale	4,[illegible]1,973	267,361
Oil, sea-elephant	590,625	25,000
Whalebone	176,141	722,651
Ambergris	94	16,900
Fur-seal pelts	92,364	484,649
Sea-elephant skins	5,000	600
Alligator hides	349,927	40,779
Otter skins	6,861	35,110
Seaweeds	900,320	36,287
Other products	4,545,829	129,391
Total	2,033,992,699	61,047,909

The following table summarizes the fish-cultural operations of the bureau:

Summary of distribution of fish and eggs, fiscal year 1908.

Species.	Eggs.	Fry.	Fingerlings, yearlings, and adults.	Total.
Catfish			277,601	277,601
Carp			350	350
Buffalo fish			40,500	40,500
Shad	760,000	79,316,600		80,076,600
Whitefish	139,266,000	384,480,000		523,746,000
Lake cisco	12,790,000	3,200,000		15,990,000
Chinook salmon	68,385,550	24,998,185	2,231,797	95,615,532
Silver salmon	296,000	13,420,714	57,932	13,774,646
Blueback salmon	75,000	69,883,305		69,958,305
Humpback salmon		7,185,748		7,185,748
Steelhead trout	333,725	1,123,146	59,000	1,515,871
Rainbow trout	830,000	253,650	2,713,600	3,797,250
Atlantic salmon		2,079,514	30,003	2,109,517
Landlocked salmon	190,000	441,281	151,526	782,807
Blackspotted trout	768,380	4,230,540	1,442,376	6,441,296
Loch Leven trout			55,012	55,012
Lake trout	2,734,000	25,267,078	3,182,080	31,183,158
Brook trout	1,473,400	6,307,048	3,471,292	11,251,740
Sunapee trout		191,736		191,736
Grayling	200,000	1,047,000		1,247,000
Pike			17,550	17,550
Crappie and strawberry bass			200,268	200,268
Rock bass			25,090	25,090
Warmouth bass			1,638	1,638
Small-mouth black bass		232,312	78,940	311,252
Large-mouth black bass		23,900	588,047	611,947
Bream or sunfish			202,810	202,810
Pike perch	218,725,000	193,438,000		412,163,000
Yellow perch	2,080,000	382,576,000	68,045	384,724,045
Striped bass		4,333,500		4,333,500
White perch	5,740,000	321,670,000		327,410,000
White bass			500	500
Fresh-water drum			26,000	26,000
Cod	3,000,000	235,365,000		238,365,000
Flatfish		389,642,000		389,642,000
Pollock		66,454,000		66,454,000
Tautog		794,000		794,000
Lobster		180,932,000	1,011	180,933,011
Total	457,647,055	2,398,886,257	14,922,968	2,871,456,280

In addition to the work of the United States Government, several of the States carry on independent fish-cultural operations, the results of which are summarized in the following table:

Number and species of fish planted by States conducting important fish-cultural operations.

Species.	California, 1906.	Colorado, 1905-6.	Maine, 1907.	Maryland, 1905.	Michigan, 1903.
Shad				11,667,000	
Pacific salmon	97,731,100				
Steelhead	352,000				
Landlocked salmon			575,380		
Various trouts	1,446,000	11,000,000	993,700		6,800,000
Lake trout			487,620		930,000
Grayling					200,000
Black bass					901,200
Pike perch					30,350
Yellow perch				121,591,000	
White perch				4,300,000	
Total	99,529,100	11,000,000	2,056,700	137,558,000	8,861,550

Number and species of fish planted by States conducting important fish-cultural operations—Continued.

It will be observed from the foregoing data that the fish-cultural operations of the United States are conducted on an enormous scale, incomparably greater than in any other country. Most of the more important food fishes and all of the prominent game fishes are included in those propagated by this bureau and the several States, but there are some valuable species which are not artificially propagated, owing either to technical difficulties, lack of facilities, or the apparent absence of the necessity.

Concerning the condition of the supply of many of the marine species of fishes it is difficult to give facts, owing to fluctuations which occur in such fisheries under the influence of natural conditions beyond man's control. There is some reason to believe that certain of the shore fisheries, as for cod, have been established and maintained largely, if not solely, by artificial propagation.

In the case of the anadromous fishes, such as the shad and the Pacific salmons, the data are definite. The shad fishery was undoubtedly maintained for many years by hatching operations solely, but recently the fishery has become so intense that most of the spawning run of fish are caught before they reach the spawning grounds and a sufficient supply of eggs for the hatcheries can not be obtained. This state of affairs has been largely induced by the indifference of the States, many of which throw the entire burden of maintaining the fishery upon this bureau while neglecting to pass laws which will permit its work to become effective. This is especially true when the shad have to pass through two or more States to reach the spawning grounds, inadequate and conflicting legislation between the interested States making abortive all efforts at efficient regulation. The salvation of the more important shad fisheries lies in bringing the States to a realization of their responsibilities, to the end of securing the passage and enforcement of efficient laws. If proper protection is afforded the spawning fish this bureau can again build up the fishery and maintain it, but at present the efforts are almost hopeless.

The same difficulty of conflicting legislation obtains in the Great Lakes. On Lake Erie, for instance, there are, including Canada, five several jurisdictions with ill-defined limits, and the consequence is that no regulations are effective. In this case, as with other northern boundary waters, the matter is now under consideration by an international commission.

The most important measures for the conservation of the fisheries lie in the production of a spirit of cooperation between the lawmaking bodies of the several States and this bureau, and it is believed that no State in which the bureau carries on fish-cultural operations should pass fishery laws without at least consulting the bureau. It would, perhaps, be well to go further and require that in case a State passes improper laws or fails to pass necessary ones, the fish-cultural operations of the Federal Government be suspended in that State until the matter is properly adjusted.

About two-fifths of the marine and fresh-water products of the United States consist of animals other than fishes, and of these the lobster is the only one which is treated by fish-cultural methods, practically all the others for various reasons being of a character to make such treatment impracticable.

Over $20,000,000 of the annual product of the fisheries is furnished by oysters, clams, mussels, and other mollusca, and sponges, which are capable of culture under private ownership. To develop these fisheries, this bureau and some of the coastwise States have long been conducting experiments and furnishing facilities, instruction, and advice, with the result that at the present time five-eighths of the entire production of oysters is derived from private beds. In those States in which oyster culture has been encouraged and developed the industry is growing, while where the natural beds are depended upon for the supply it has decreased heavily during the past 15 or 20 years. The work carried on by this bureau and the shell-fish commissions of the several States assures that this fishery, producing about $17,000,000 at first value to the fishermen and two or three times that amount ere the product reaches the consumer, is not only in no danger of failure, but is destined to future development commensurate with the growing demands of the country.

The bureau is also conducting experiments in pearl-mussel culture in the Mississippi Valley, which, it is confidently believed, will perpetuate the button industry, worth about $500,000 to the fishermen and about $6,000,000 in finished products, and which under present conditions is doomed to speedy extinction. It has also recently developed a system of sponge culture which will prevent the extinction of the sponge fishery of Florida, now producing a raw product valued at from $500,000 to $1,500,000 per year. Other works of a similar character have been completed or are now under way.

In regard to the changes in the distribution of fishes due to mining, irrigation, and drainage enterprises, and the possibility of utilizing such projects in the increase of the supply of food fishes, the bureau can give no definite information. The importance of these subjects is fully appreciated, but no investigations relating to them have been conducted. The lakes, reservoirs, and canals established in irrigation work can undoubtedly be made important local sources of food supply, but each case will have to be made the subject for special inquiry and considered on its merits. The bureau can do nothing more than theorize at this time.

The pollution of streams by sawdust, industrial wastes, and the discharge of water from mills, most of which abuses are preventable, has received some attention at the hands of this bureau, but should be the subject of further inquiry. That these pollutions do considerable injury to some of our minor fisheries is certain, and together with the results of deforestation they have ruined many streams formerly teeming with the best of our game fishes.

THE TIMBER AND STONE ACT, AND THE COMMUTATION CLAUSE OF THE HOMESTEAD ACT.

By H. H. Schwartz,
Chief of Special Agents, General Land Office.

THE TIMBER AND STONE ACT.

June 3, 1878, Congress enacted a law providing for the sale of lands chiefly valuable for timber or stone at "the minimum price of $2.50 per acre." It applied to the States of California, Oregon, Nevada, and the then Territory of Washington. The act was later extended to all of the public-land States.

I am advised that the recommendation of the Commissioner of the General Land Office that this law be enacted, and the discussions in Congress in its consideration, disclose that the act was intended to provide wood lots for settlers and preemptors upon whose lands the supply was insufficient, and timber for local use at a fair price.

In practice, however, this law has resulted in the sale of over 12,000,000 acres of valuable timber lands, of which fully 10,000,000 acres were transferred to corporate or individual timber-land investors by the entrymen. These lands brought to the people or General Government a gross sum of $30,000,000. At the date of sale they were reasonably worth $240,000,000. The profit of over $200,000,000 went not to the needy settler engaged in subduing the wilderness, but to the wealthy investors. Not over a fractional part of 1 per cent of the timber purchased from the United States under this act is held, consumed, or even cut by the men and women who made the entries.

The law requires, and each applicant makes, an oath containing among other things the following:

"That he does not apply to purchase the same on speculation, but in good faith to appropriate it to his own use and benefit; and that he has not directly or indirectly made any agreement or contract in any way or manner, with any person or persons whatever, by which the title he might acquire from the Government of the United States should inure, in whole or part, to the benefit of any person except himself."

The Supreme Court, in United States *v.* Budd (144 U. S., 154), holds that an entry and purchase made with intent to sell at an advance if the market improves, and with no intent to use the timber itself, is not a "purchase for speculation."

Up to December 1, 1908, the department assumed that the words "may be sold * * * at the minimum price of $2.50 per acre" means $2.50 per acre absolutely, as if the words "the minimum" had not been inserted.

So that since June 3, 1878, citizens and those who have declared their intention to become such have had presented to them a law under which they may lawfully enter lands worth from $2.50 up to $200 per acre, upon the following terms:

First. At $2.50 per acre.

Second. With intent to sell the same at an advance to the first buyer, and with an intent never to use the timber thereon.

With enough entrymen possessed of $500 each, or credit to borrow that amount, and a prospective buyer at a small advance, the machinery is complete for transferring title from the Government or general public to the single corporate or individual investor. The process has been automatic, and in most cases neither fraud, perjury, or false swearing is needed.

In my ten years' experience in the Government field service I have seen several heavily timbered regions suddenly go from the Government to practically single private ownership.

The process is like this:

A timber scout or estimator reports to his employers the general situation and extent of some well-timbered region. Investigation has discovered enough timber and a present or prospective market warranting more or less extensive investment. Lands already in private ownership are purchased, probably a sawmill installed, and actual operations begun. The company or investor secures estimates on the timber on each 40 acres of vacant lands. If a settler or timber and stone applicant makes final proof, he is offered a price from $100 to $500 over the cost of the land to him. At once the community—and the relatives and outside friends of the community—learns that there is a market for timber claims and that a man with $500 can practically double it in ninety days by the simple process of entering a piece of land at $2.50 and selling it at $5 or $6 per acre.

Here again the Supreme Court, in the case of United States *v.* Budd, above cited, has made plain the operation of this law. The majority of the court say one

> might rightfully go or send into that vicinity and make known generally or to individuals a willingness to buy timber land at a price in excess of that which it would cost to obtain it from the Government, and a person knowing of that offer might rightfully go to the land office and purchase a timber lot from the Government and transfer it for the stated excess without violating the act of June 3, 1878.

Since January 6, 1908, the person entering timber lands where some investor has given his notice of a willingness to buy all lands entered need not even have the $500 with which to buy, nor need he have credit upon which he may borrow that amount. The Supreme Court of the United States, in the case of United States *v.* Williamson (207 U. S., 425), decided upon the above date, holds that an entryman who has filed his sworn statement designating the particular tract he desires to purchase may, between the date of so filing and the date of actual payment—the sixty or ninety days during which he advertises his application to purchase—lawfully contract to sell or convey the land after patent issues. In other words, he may enter the lands with an intent to sell at once if he can make a profit; the corporate or individual investor may inform him that he will buy at a profit; after the entry is made, and before the applicant advances a dollar of the purchase price, entryman and prospective purchaser may contract to convey and the investor bind the bargain by depositing with entryman's attorney enough of the sale price to pay the Government for the land, and the identical money advanced on the lawful contract to sell is paid over the counter of the land office by entryman's attorney at final proof.

There is no fraud in the entryman; no risk to the investor; and a single concern may secure a wood lot of 100,000 acres in less than a year, at a profit of $1,000,000 to the corporation and at a loss of the same sum to the general public, which is the Government.

I recall a specific instance in the Susanville and Redding districts, California, where a single investor, in the course of probably three years, acquired approximately 700,000 acres of heavily timbered lands, a large amount of which was secured under the timber and stone act.

In another large operation in central Oregon trainloads of women school-teachers were shipped out from Minnesota and entered lands under the timber and stone act. A hundred citizens of Oregon made like entries. These lands were then transferred to a timber investor from Minneapolis, Minn., transfers going to him by deeds to a corporation. The articles of this incorporation were peculiar. They provided that only the president need own stock therein; its officers were composed of the president (who was the investor) and his wife and son, who were, respectively, secretary and treasurer.

During the past ten years there have been like individual operations in Montana, Idaho, Washington, and Colorado.

But if this land is worth from $10 to, say, $30 per acre for its timber, why does the entryman sell for $5? Standing alone it may be worth only $1 or $2 an acre, but as part of a large group of claims it may be worth $50 an acre. It costs money to establish logging camps, build logging roads, and erect sawmills, and find a market for the product. The owner of a single 160-acre tract could not manufacture lumber for the market. It is when the initial costs are chargeable to a large number of claims that the actual timber values appear.

There is another and controlling reason why the individual must sell, even if he has the means to hold the land as an investment. The concern owning the milling outfit or controlling the general situation may log its surrounding lands and leave him with an isolated 160 acres of timber, with no market for so small a quantity and no buyer who could thereafter log it at a profit. Also, the general system of logging is such that fire usually runs over the cut-over lands because of litter left by the loggers. That fire will destroy what few small stands of timber remain.

There are, of course, many frauds and perjuries in operations of the timber and stone lands; but they are relatively few compared to the vast number of entries made.

Of late years we have large numbers of stone entries under this act. These are usually fraudulent, with perjury involved. There is, however, no money or value loss to the Government. These stone entries are mostly in the arid and grazing regions, for lands only fit for grazing and seldom worth more than the minimum $2.50 price.

The fraud is in the oath that lands are chiefly valuable for stone. Usually the lands are more or less isolated tracts, so geographically related to the ranch of the applicant as to make it practically necessary for him to own the tract to "round out" his holdings, make it possible to fence his own land without fencing government land, secure an outlet to the open range, or some similar need.

In pursuance of a recommendation by former Commissioner Ballinger, the department, on December 1, issued new regulations requiring as to all future timber entries that the land shall be appraised for land and timber value and then sold only at such value.

THE COMMUTATION CLAUSE OF HOMESTEAD LAW.

There is no such thing as a separate and distinct law authorizing the entry of agricultural land with intent to commute. There is the general homestead law, with minor qualifications as to Indian lands. In all, however, the applicant must swear, among other things, that he takes the land in "good faith for the purpose of making a home for himself," and not for speculation or sale. And the law under which he makes his oath and original entry requires five years' residence and cultivation.

Congress, recognizing that misfortune or change of circumstances might be the lot of any settler, has provided that any homestead claimant may, after fourteen months' residence and cultivation, commute his entry—that is, purchase the land at $1.25 to $2.50 per acre.

It has been my experience and observation in ten years of field service that the commuted homestead is almost universally an entry initiated with a full intent never to make the land a home. Before the timber and stone law was extended to all public-land States the commutation clause in the homestead law was the vehicle through which timber was fraudulently acquired from the Government.

It has been my personal experience to examine solid townships in northern Wisconsin, in which practically all the even-numbered sections had been acquired under the homestead law, quite generally commutation. The timber had been cut off after patent, and yet not a single voter or inhabitant could be found in the township. The Government got $400 a quarter section for lands frequently worth from $10,000 to $20,000. More recently actual farmers have purchased these stump lands from the mill companies.

"Commutation" is the clause in the homestead law under which citizens who are not farmers or ranchers, and who have no intention of ever becoming such, enter agricultural or valuable timber lands.

While the wording of the original commutation clause required fourteen months' residence and cultivation, the department until recently held that as homestead applicants are given six months from original entry in which to establish themselves upon the land, therefore eight months' residence immediately after the expiration of this six months complied with the law as to fourteen months' residence. That construction has been given the force of actual law by the past Congress as to former entries.

Actual inspection of hundreds of commuted homesteads shows that not one in a hundred is ever occupied as a home after commutation. They become part of some large timber holding, or parcel of a cattle or sheep ranch.

As distinguished from the timber and stone entries, commuted homestead entries are quite frequently fraudulent in their inception: in that the claimant swears falsely when he or she says that the land is taken in good faith, for the purpose of making it a home, and that there is an intent to reside upon and cultivate the land.

In the bulk of cases in which homestead entries are commuted it it found that the entrymen, both at the time of entry and at the time of proof, are engaged in some business other than agricultural or grazing. They are usually merchants, professional people, schoolteachers, clerks, journeymen working at trades, cow punchers, or sheep herders. Generally these lands are sold immediately after final proof. There are few commuted homesteads upon which there is residence after final proof; and it is seldom that there is further pretense of cultivation.

Since the passage of the first commutation clause in the homestead law in 1862 there have been practically 35,000,000 acres of land acquired thereunder. The Government received probably $70,000,000 for lands worth over $350,000,000 at the time title left the United States.

The average yearly acreage commuted has been approximately 600,000. It is noted, however, that in the past few years the acreage of land annually commuted has largely increased. In 1905 there was a slight excess above 1,400,000 acres sold; in 1908 the acreage had increased to 3,124,277.

This increase coincides with the closer inspection and enforcement of the public-land law. Because of the inspection, those who are "dummies" for investors in timber, or cattle, or sheep concerns, and those who have no actual intent to make homes upon the land, are now unable to give such physical presence and cultivation to the land as will permit them to make a five-year proof. As a consequence they put in eight months time on the land, and thereupon commute. At present fourteen months actual residence is required.

I have no recommendation as to what land laws shall be enacted, but it is my opinion, after years of close personal application to this subject, that if there is one need from Congress, it is that it shall provide a reasonable fund to enable the Commissioner of the General Land Office to keep in touch with the actual conditions in the field, and make proper investigations of the manner in which public-land laws are being complied with on the one hand and abused on the other. Lands valued at hundreds of millions of dollars are annually passing from the United States to private holdings. There is an appropriation of $500,000 for this year (heretofore never more than $250,000) to cover inspection and enforcement of the law in the immense area of the public-land States.

The Government is merely the people, and whatever of the public land is fit for the home of a citizen should be held until citizens establish homes thereon. The settler should have his home free and without unnecessary restriction. But, as to lands valuable only for their timber, coal, oil, gas, or other natural resources, we may well consider whether it is not equitable that the individual who seeks for himself that which now belongs to the whole people, shall not give the people value for value in the exchange. There is no method of compelling this fair exchange other than providing the executive officers charged with the enforcement of the law with sufficient men and funds to properly and efficiently transact the people's business.

SPECIAL AGENT WORK OF THE GENERAL LAND OFFICE.

This is a statement showing approximately $110,000,000 worth of public lands believed to have been fraudulently acquired. There is reasonable prospect of recovering much of this land, if prompt action is taken.

For the fiscal year ending June 30, 1908, Congress appropriated $250,000 for the protection of public lands. A like sum had been appropriated for the year ending June 30, 1907. Public land investigations, increasing public sentiment for better protection of the national resources, and extensive discussion of these matters in publications, during the past five years, have resulted in many thousands of informations being filed in the General Land Office, charging land frauds. Many thousand cases of violation of land laws have also been brought to the attention of the Government through investigations by special agents; also, special employees of the Department of Justice have furnished the General Land Office with information in important cases.

The foregoing conditions produced great congestion in the work devolving upon the land field force. The General Land Office, local offices, and field agents receive annually thousands of complaints against claims and entries under the settlement laws. Experience shows that only about one-half of these complaints are justified. The examination of such cases has been the principal field duty—to the end that the settlement claims and entries may proceed without delay. However, the great number of extensive frauds demanding immediate action and necessarily consuming months of time in investigations and subsequent attendance in court trials leave to-day over 16,000 settlement claims suspended on complaint, out of the total 32,226 cases of all kinds pending December 1, 1908. The nature of the "necessity" for prompt action in some of the larger cases is shown in United States *v.* Juanita Coal and Coke Company, and United States *v.* Utah Fuel Company, involving lands worth $2,500,000. In these two cases the evidence of the fraudulent acquisition of these lands was finally uncovered in November last. Suits were filed December 7, 1908, and the statute of limitations would have prevented suit on December 8, 1908; likewise, in the Oregon cases against C. A. Smith et al., involving timber worth about $1,000,000, the investigations were completed, and suit was filed in May, 1908, within a few weeks of six years after patent issued. Suit can not be brought against a patent six years old.

With the $250,000 appropriated for the fiscal year ending June 30, 1907, the field force investigated and disposed of practically 6,500 cases, collected from trespassers $284,470.03, recovered 390,240 acres of land of about $2,186,400 in value, and secured the conviction in criminal cases of 138 defendants.

The present reorganization of the field force and general methods of handling the investigations in relation to public lands dates practically from the beginning of the fiscal year 1907–8. The work performed and the results accomplished in protecting public lands, recovering public lands fraudulently acquired, and prosecuting parties guilty of crimes in relation thereto from July 1, 1907, to December 1, 1908 (seventeen months), will therefore be treated as a unit. The amount appropriated for carrying on the work for the seventeen months was $500,000, viz, $250,000 for the fiscal year ending June 30, 1908, and $250,000 was expended for the first five months since that date. With this expenditure of $500,000 the following results have been accomplished:

Absolute recoveries.

10,033.07 acres of patented lands recovered (including coal lands); estimated value	$824,555.35
618,240 acres of entered unpatented lands recovered; value	3,547,100.00
Collected from timber trespassers	136,694.79
Fines collected	8,597.94

The foregoing comprise absolute recoveries to the United States of $4,516,858.08 in money value, which is $4,016,858.05 in excess of the total appropriation expended in the work. This is not, except the fines and timber trespass, money returned to the United States Treasury; but it is lands of that value restored to the public domain where the honest purchaser or settler may acquire it; and the present administration of the public-land laws is such as to prevent the recurrence of illegal acquisition. Also, the subsequent sale of the recovered coal and timber lands—now for the first time sold upon appraisal—will result in such increase in cash returns to the Treasury as will exceed the expense of recovery.

The absolute recoveries, however, constitute but a small part of the work performed and being performed. The detailed summary hereto attached shows information in the possession of the Government which may lead to the recovery of moneys and lands reasonably worth in excess of one hundred million of dollars. How effective these recoveries shall be depends upon the men and funds available for carrying on the work.

A comparison of the number of cases actually investigated in the field and reported on shows that, during the fiscal year ending June 30, 1907, 6,500 cases were examined at a total expense of $250,000, while during the seventeen months ending December 1, 1908, 28,183 cases were examined, at a total expenditure of $500,000. Taken as a whole, the work was measurably similar, and there is a consequent showing of increase in efficiency of over 100 per cent since the general reorganization of the special service.

During the past seventeen months, special agents have caused to be released from unlawful inclosure a total of 1,007,684 acres of vacant public lands. These lands were restored to settlement and the open range.

We have secured 94 convictions for violation of the public-land laws. In a large number of these cases the fines were collected, and in important cases imprisonment sentences were imposed. A tabulated statement showing details of these convictions is attached.

The field force have also examined public lands covered by rights of way, easements, and privileges granted, of which 98 were found to be either fraudulent or illegal, and adverse proceedings have been or will be instituted to free the public lands from such easements now resting thereon.

Actual investigation and examination have also been made of nine Carey Act projects, involving 199,259.18 acres. These investigations disclose projects covering 62,070.99 acres, in which the land has not been reclaimed, and in which conditions warrant action looking to the recovery of lands, either from lack of water or because lands are not desert in character. Other examinations are in progress. These do not include original examinations upon applications to select, such examinations being made by inspectors of the department.

The expectation of the General Land Office, as expressed by the commissioner to the Committee on Appropriations when considering the sundry civil bill for the year ending June 30, 1909, that an appropriation of $500,000 per year for two years would clear up the then accumulated work, will be realized.

However, the investigations of the past two years by special agents, aided by an aroused public sentiment, have produced evidence and information of wholesale and astounding frauds upon the public lands, and such cases necessarily require much time from the field force. As a result, we have of record in the special-service division of this office the 32,000 distinct cases demanding further field action, notwithstanding that during the past seventeen months there have been investigated a total of over 28,000 cases.

The magnitude of the task imposed upon the General Land Office in some of these cases will be best appreciated by example:

In a single suit to recover coal lands having a commercial value of millions of dollars it may become necessary to take the following steps:

First. Examine all of the records and correspondence in one or more of the local land offices and in the General Land Office in relation to probably 50 distinct entries of land; this examination develops the coincidence of claimants and witnesses, attorneys of record, notaries and commissioners before whom papers were executed, with a subsequent examination of probably 50 to 100 witnesses now scattered throughout the United States, and who have in one way or another been connected with the proceedings by which the Government lost title to the lands. These witnesses embrace coal experts employed by the corporations to prospect the lands, dummy entrymen, attorneys, notaries public, United States commissioners, and the various witnesses required to the different filing papers.

Second. It is necessary to examine and abstract the titles to these lands as they appear of record in the office of the recorder of deeds in the different counties.

Third. There follows the investigation of the organization and development of the corporations and holding companies who have taken over the title and who by trust deeds and mortgages endeavor to forestall recoveries by pretended purchases or incumbrances for value. This branch of the case frequently occupies months of time by men expert in real and corporate law, and frequently develops three or four companies holding titles, mortgages, trust deeds, or bonds predicated upon trust deeds, all intended simply to involve the title. In other cases subsequent transfers have proved to be bona fide.

Fourth. To the end that the value of the lands may be determined, in the event that some one of the interested corporations is able to make good its claim of innocent purchaser, and the Government is thereby driven to a judgment for damages sustained, in lieu of the recovery of the lands, it becomes necessary for men expert in coal mining and geology to make extensive field examinations.

Fifth. As these coal companies have frequently been operating from two to five years, it also becomes necessary to determine the amount of coal taken from the lands, and its value in the different situations; which may, according to the event of the suit, fix the rule of damages the Government shall recover for probably several millions of tons of coal unlawfully taken from the lands.

It will be seen that a proper presentation of the Government's case in each one of a dozen suits similar to the foregoing may well require the entire time for from three to six months of a half dozen men.

Example might also be cited of some of the more determined and persistent violators of the act to prevent unlawful occupancy of the public lands, known as the fencing law: A single case reported from Oregon involved over 85,000 acres of government land in one inclosure; in addition thereto there were a large number of fraudulent or dummy entrymen on some of the lands inclosed. If the Government expects to present such a case as this to the court or jury, with a showing which will warrant anything more than a nominal fine (which means a very nominal charge for pasturage on the public land, and the exclusion of the general community from free range), it becomes necessary, not only to show the inclosure, but to show it in detail; probably survey, chain, and subsequently plat over 100 miles of fence; investigate into the circumstances and bona fides of probably 50 to 100 entries, of one kind or another, made within the inclosure, supposedly for the benefit of the live-stock company; also interview from 50 to 100 witnesses, the dummy entrymen; the men who built the fences, to determine when they were built, and who paid for them; cow punchers, and small cattlemen, for proof that the large company controls the inclosure, and that the stock of small individuals is driven therefrom; in some cases the settlers are forcibly prevented from investigating or occupying the lands.

Again, there are conspiracy timber cases which may well take the time for from one to three months of three or four men. Along this line the land office has single cases of over 200 entries of more than 32,000 acres of land. Combinations are frequently so well organized, and so aided by defective public-land laws, as to present an almost impossible task in securing evidence or recovering lands worth hundreds of thousands of dollars. It may become necessary to assign an agent to a single conspiracy case and keep him there to the exclusion of everything else for a period of three or four months, and in certain phases of the investigation the services of other agents are required. A single timber trespass case may require a crew of men for weeks. One case investigated this year shows trespass of timber covering 7 miles of territory and timber taken of over $200,000 value. The land was unsurveyed and it became necessary to run lines and scale up this entire trespass, measuring it stump by stump. It is an old trespass, but the Government may still recover, there being no statute of limitations against a money demand.

These examples furnish indication of what the field force has done in making recoveries mentioned in the earlier part of this statement, and what now devolves upon it in successfully prosecuting the larger cases involved in the total of over 30,000 cases pending.

Following is a summary of most of the larger cases affected by charge of fraud or illegality now pending. They are here set up by State or field divisions. Details of identification and names of parties are omitted in cases under investigation for the reason that parties are entitled to such protection until investigation develops facts warranting their presentment to a proper tribunal, and on the other hand present publishing of details would generally embarrass further inquiry in a case:

Alaska.

1. Probably 500 coal claims worth at least $200 per acre on basis of 1 cent per ton	$16,000,000
2. Pending timber trespass	200,000

Arizona.

IN UNITED STATES COURT.

3. United States *v.* Grand Canyon Lime and Cement Company, to recover for timber trespass	40,000

California.

IN UNITED STATES COURT.

1. United States *v.* Hyde, Benson, et al., to recover 11,040 acres of land patented under scrip selections	110,400
2. United States *v.* English, embezzlement, indictment, amount of shortage	15,000
3 United States *v.* Dwinell et al., conspiracy, indictment, involving 1,120 acres of timber land worth	22,400
4. United States *v.* McPherrin, and 7 others, indictment, conspiracy, involving 3,840 acres of land worth	162,000

IN DEPARTMENT.

1. United States *v.* H. H. Yard et al., 200,000 acres of heavily timbered lands covered by placer location in forest reserve	5,000,000
2. United States *v.* Golden and Darby, heavily timbered lands covered by placer mining location	80,000
3. Thirty-two timber trespass cases involving	100,000

Colorado.

IN UNITED STATES COURT.

1. United States *v.* Juanita Coal and Coke Company, to recover 2,800 acres of coal lands, value $300 per acre	840,000
2. United States *v.* Utah Fuel Company, to recover 5,000 acres of coal lands valued at $300 per acre	1,500,000
3. United States *v.* New Mexico Lumber Company, to recover 8,640 acres of best timber in Colorado, value $50 per acre	432,000
4. United States *v.* Barnes et al., timber trespass	50,000

IN DEPARTMENT.

1. One group of coal entries	1,600,000
2. One group of timber land entries	860,000
3. One group of lieu land selections	3,000,000
4. Case of lands	2,000,000
5. One group of coal entries	1,200,000
6. One group of coal entries	1,280,000
7. One group of coal claims	1,000,000
8. One group of coal claims	750,000

9. One group of agricultural entries on coal lands	$4,000,000
10. One group of timber and stone entries	440,000
11. One group of timber and stone entries	200,000
12. Six timber trespass cases	335,000
13. Two cases of coal trespass, at $1 per ton	3,500,000

New Mexico.

IN UNITED STATES COURT.

1. Suits to recover 560 acres of coal lands	56,000
2. United States *v.* Coolidge et al., 640 acres of highly improved, irrigated, agricultural lands, present value over $100 per acre	64,000

IN DEPARTMENT.

1. Group of 1,120 acres of coal lands, worth $50 per acre	56,000
2. Four hundred and eighty acres in coal entries, $100 acre	48,000
3. A case of 12 coal entries for corporation, 1,920 acres, at $50 acre	96,000
4. Group of 14 desert entries, 2,240 acres, at $2.50 per acre	5,600
5. One timber trespass of 70,000,000 feet; $2 per thousand	140,000
6. One trespass case	11,050
7. Unlawful inclosure 120,000 acres	

Michigan.

IN DEPARTMENT.

1. One group of coal and timber entries of 5,400 acres, value $10 per acre	54,000
2. Fifteen timber entries	6,000
3. Two timber trespass cases	27,000

Minnesota.

IN DEPARTMENT.

1. Fourteen timber trespass cases	112,117
2. Indian reservation lands, erroneously classed swamp, timber, value	350,000

Montana.

IN UNITED STATES COURT.

1. United States *v.* B. F. Howard et al., to recover value of timbered lands entered under the mining laws	40,000
2. United States *v.* Anaconda Copper Company, timber trespass	64,934

IN DEPARTMENT.

1. United States *v.* McCune et al., trespass of 720,000 cords of wood, stumpage value	360,000
2. Eighty tracts of coal land entered under the timber and stone act, actual value $100 per acre	1,280,000
3. One lot 4,000 acres agricultural land, worth $25 per acre, acquired under the desert-land act	100,000
4. One case involving lands worth	100,000
5. Timber trespass in Missoula district, stumpage	500,000
6. One railroad and lumber timber trespass, Missoula district	500,000
7. Timber trespass case, Billings district	50,000
8. Land conspiracy, lands at $5 per acre	100,000
9. United States *v.* Libbey Placer Mining Company, timber lands held under mining locations	250,000

Nebraska.

IN DEPARTMENT.

1. Conspiracy of 4,000 acres desert land, value $5 per acre	$20,000
2. A case of 800 acres coal lands acquired by nonmineral entry	80,000
3. A conspiracy case; 18,000 acres	90,000

Nevada.

IN UNITED STATES COURT.

1. United States *v.* Central Pacific Railway Company and Southern Pacific Railway Company, 4 suits to recover mineral lands; lands have proved value in many operating mines of over	25,000,000

IN DEPARTMENT.

1. Rhyolite Township lands, group of lands held under mining locations	375,000
2. United States *v.* Central Pacific Railway Company, to recover about 300 acres of mineral lands erroneously acquired under its grant; a very conservative commercial value is	15,000,000

Oklahoma and Kansas.

IN DEPARTMENT.

1. Nine unlawful inclosures, including 302 alleged fraudulent entries of 51,720 acres, and 66,000 acres of vacant government lands; value of entered lands	517,000

Oregon.

IN UNITED STATES COURT.

1. United States *v.* Kribs et al., to recover timber lands having commercial value of	200,000
2. United States *v.* C. A. Smith, two suits to recover timber lands having commercial value of	750,000
3. Twenty-one allied suits to cancel 47 entries of heavily timbered lands	235,000

IN DEPARTMENT.

1. Case involving 75 timber entries	200,000
2. Case involving block of pine, heavy stand. 10,000 acres	250,000
3. Two unlawful inclosures of over 140,000 acres vacant land	
4. One lot of coal entries on timber land in national forest	200,000

Utah and southern Idaho.

IN UNITED STATES COURT.

1. United States *v.* Utah Fuel Company, and Pleasant Valley Coal Company et al., suits to recover title to over 40,000 acres of coal land, at $200 per acre	8,000,000
2. Court cases to recover 22,000 acres of heavily timbered pine lands worth about $30 an acre	660,000

IN DEPARTMENT.

1. About 20,000 acres coal lands held by nonmineral entries, worth about $100 per acre	2,000,000
2. One case of 3,500 acres of coal lands	70,000
3. Unlawful inclosure of 160,000 acres of vacant lands	
4. About 800 nonmineral claims to lands valuable for coal, at $50 per acre	6,000,000
5. Four hundred and eighty-eight state selections pending for examination	

Washington and northern Idaho.

IN UNITED STATES COURT.

1. United States *v.* Flynn, to recover 160 acres of improved lands	$8,000
2. United States *v.* Multnomah Mining and Development Company, to recover 256 acres of land	10,000
3. United States *v.* Barbee, to recover 640 acres coal lands	64,000
4. United States *v.* Kettenbach et al., to recover 8,481 acres of timbered lands, worth about $20 per acre	170,000
5. United States *v.* Hope Lumber Company, timber trespass	7,000
6. United States *v.* Bunker Hill Mining Company	

IN DEPARTMENT.

1. To recover 6,000 acres timber and fruit lands in the Colville Indian Reservation, held on mining claims	300,000

Wisconsin.

1. Three timber trespass cases	20,500

Wyoming.

IN UNITED STATES COURT.

1. United States *v.* Union Pacific Railway Company, to recover 5,186 acres of coal lands, at $300 per acre	1,555,840
2. United States *v.* Hyde, Benson et al., to recover 400 acres of agricultural land, at $10 per acre	4,000

IN DEPARTMENT.

1. One timber trespass, stumpage	350,000
2. One railroad timber trespass	45,000
3. Four trespass cases, value	47,432
4. One thousand seven hundred and sixty acres unlawfully acquired	15,000
5. United States *v.* Dally et al., to recover 9,500 acres of coal land, worth $150 per acre	1,425,000
6. Lander Coal case, to recover 2,500 acres of coal land, worth $150 an acre	375,000
7. Alleged attempt to acquire 2,560 acres of coal land, worth $200 per acre, by dummy system	512,000
8. Alleged attempt to acquire 2,240 acres of coal land, worth $200 per acre, by combination	448,000

Southern States.

1. Ten timber trespass cases involving	160,000
2. United States *v.* McKaskell Company	20,000
3. Florida, 5,000 acres timber land	50,000
4. Mississippi, entries	200,000
5. Agricultural entry on oil lands	20,000
Total	114,733,273

There are also set for trial and hearing 1,021 cases before local land offices, upon reports by special agents and forest officers, as follows: Alaska, 1; Oregon, 141; California, 84; Washington, 25; Montana, 227; Colorado, 77; Arizona, 41; Wyoming, 101; Nebraska, 37; Minnesota, 7; Michigan, 1; Wisconsin, 3; North Dakota, 39; South Dakota, 26; Arkansas, 47; Louisiana, 11; Idaho, 25; Utah, 6; Kansas, 13; Oklahoma, 6; New Mexico, 71; Alabama, 11; Florida, 10; and Mississippi, 8.

There are also pending in the Department of Justice and United States courts, upon reports by special agents, the following cases:

Timber trespass	161
Suits to recover lands	490
Unlawful fencing of public lands	122
Criminal cases	321
Total	1,094

These are all cases of merit to be tried. The old business accumulated on the dockets has been dismissed wherever facts warranted.

The system of handling court cases heretofore lacked proper check between the Department of the Interior and Department of Justice. There was no automatic card or record of each case to call it, and no effective order compelling whatever additional action or investigation each case demanded. To meet this situation and clear the court dockets of cases fatally defective, and ascertain what was yet required in other cases, the Secretary and Attorney-General had appointed in each court district a committee consisting of the United States attorney, a Department of Justice inspector, and a special agent of this office. This committee took up and considered each case on the court dockets or pending for suit. Cases were found of twenty years' standing; particularly in the southern jurisdictions were found many old timber-trespass cases wherein the defendants had long since disappeared. These committees recommended the dismissal of all cases wherein it was found no reasonable basis for assuming conviction or recovery could be had. As a result, there were dismissed 245 criminal cases; 71 timber-trespass civil cases; 18 cases to recover lands, and 4 fencing cases. The remaining 1,094 cases will require heavy drafts upon the time and expense of the field corps. Some of these are old cases which are now found to require additional work. Although the above cases are now in the hands of the Department of Justice, our agents must attend terms of court as witnesses; and, where additional evidence is required, the United States attorneys naturally expect agents who were familiar with a case from its inception to supply whatever further information is required.

For the Attorney-General to require his own agents to secure additional information involves the loss of time and money incident to putting an investigation into new hands not familiar with the records, facts, and witnesses. Naturally, we must remain with the case to the end.

Record of criminal cases from June 30, 1907, to June 30, 1908.

The question of values above mentioned is matter of opinion. Much of the coal is the very best in America; I have valued it at $150, $200, and $300 per acre. Should the Congress conclude to separate the coal from title to the surface in disposing of lands, and permit coal mining on a royalty basis of only 10 cents per ton, these lands would produce $1,000 per acre for 10-foot veins, this on a basis that 10 out of 18 tons are actually mined. Many of these lands in the States run from 15 to 25 feet in high-grade, workable coal; in exceptional cases, fields carry coal measuring 30 and 40 feet in thickness; in Alaska, there are pending coal entries upon coal measures as high as 60 feet thick clear coal in one vein.

The question of timber values varies according to market and locality. In the Smith cases, there are lands with 3,000,000 to 10,000,000 feet to the quarter, worth on the stump $2 and $6 per thousand feet, or over $200 an acre. East of the Cascades the timber runs much lighter, and the good timber land fraudulently acquired several years ago has from 1,000,000 to 3,000,000 feet a quarter section, generally, and is worth about $4 per thousand, or, about $50 per acre. None of these lands are culls. Later entries are generally of less value.

As to the value of mineral lands in Nevada, the estimate of $15,000,000 and $25,000,000 of demonstrated values is based on careful field examination by competent mining agents. The New York Engineering and Mining Journal has estimated these lands at $100,000,000. This refers to the particular lands already examined.

This is a summary of the work performed, and the task ahead of the special agents, given in such detail as the state of work will permit, and intended to show the value of the services being performed by special agents of the General Land Office.

This letter lays considerable emphasis upon the money value of the public domain and its natural resources. Important as is this feature of our work, it is second to that of preserving for home builders the lands fit for homes and aiding to the fullest extent every settler in his effort to establish himself upon the public domain. The positive instruction of Secretary Garfield to his field force is that, although agents are to use every endeavor to prevent land frauds and crimes, they must always keep in mind that their principal task is to speedily reach and investigate the complaints involving settlement rights, to the end that the honest settler be not harassed or delayed. To that end, as before stated, investigation has clear-listed over 13,000 cases since July, 1907. That work of itself has justified the wisdom of Congress in increasing the appropriation under this head. Experience shows that, with hardly an exception, agents have followed instructions and have given the settler a favorable report wherever good faith was shown and a real intent to make a home could be drawn from all the circumstances of the case. On the other hand, they have uniformly reported the facts as they found them, or understood them, without fear or favor, conscious of the sufficient support of their superior officers. Some of the agents new to the work may have made errors of judgment; and in any case where complaint is made that the agent's findings are not warranted or that his actions are not proper, independent investigation is made, or a hearing is had, to the end that no injustice be done either to the entryman or the agent.

In addition to the regular work of advancing the settlement of the public domain, it will be seen from the foregoing summary that, through the arms of the field force, officers and employees, it is necessary to recover over $100,000,000 worth of the people's property, alleged to have been illegally or fraudulently acquired by private individuals and corporations. The last Congress raised the fund for this work from $250,000 to $500,000. Some of the larger cases cover lands patented years ago, and the knowledge or information of fraud is but recent. It is really a race with the statute of limitations in many large matters. A most cursory knowledge of the necessity of immediate action, action before the statute of limitations intervenes, and witnesses die, or memory clouds, show the inadequacy of $500,000 per annum to recover a hundred million in jeopardy. There is need for $1,000,000 for this work. It will be returned tenfold in recoveries of national resources now held unlawfully by private parties.

NOTE.—March 3, 1909, Congress appropriated the $1,000,000 asked for this work.

RIGHTS ANALOGOUS TO SCRIP.

By S. W. WILLIAMS,
General Land Office.

Scrip and the rights analogous thereto mean the right to locate or exchange lands, the basis for such right usually consisting of other lands to which the party claiming the scrip had some right, but for some reason could not acquire title; or else of land in private ownership, which, under certain conditions, may be exchanged with the Government for other lands.

Scrip rights, however, are not always based upon the loss or exchange of other lands, for Congress has granted scrip in the form of bounty land warrants for military service. Akin to this is the soldier's additional homestead right granted by the act of June 8, 1872 (17 Stats., 333).

The term scrip, of course, means a writing of some sort, but in land practice it has grown to represent the right to locate land even where no actual certificate, warrant, or other paper is issued. Thus the right of a soldier or his assignee to make an additional homestead entry, or the right of the owner of lands in a national forest, under the act of June 4, 1897 (now repealed), to exchange such lands for others, is termed scrip, though in neither case was it usual for the Government to issue any certificate or other writing as evidence of such right.

In other instances, as in the case of surveyor-general scrip under the act of June 2, 1858, supreme court scrip under the act of June 22, 1860, and other cases, it was made the duty of some designated officer of the Land Department to issue the written certificate or warrant.

It may be said that it is the office of scrip to enable its owner to acquire title to public lands without the necessity of residing, settling, or making any improvements whatever upon the lands to be acquired; and the quantity of land which may be located is determined only by the quantity of scrip which can be secured. The practice of selling the public lands indiscriminately to anyone possessing the necessary money to pay the purchase price (which I may say in passing has always been grossly inadequate) was abandoned years ago, and now only those possessing certain qualifications, and generally upon conditions more or less arduous, may secure lands by the payment of money, and even then only in limited quantities.

This, together with the fact that scrip is usually transferable by a simple assignment, renders it very valuable, and an object of eager search. Its importance as a factor in the acquisition of public lands becomes at once apparent, and the effect upon the morals of the land-seeking public is equally noticeable.

Lawyers who might otherwise have become an honor to their profession have degenerated into speculative scrip dealers. Men of good standing in their communities have not hesitated to commit perjury in behalf of their friends who supposed, from a mere similarity of names, that they were entitled to certain rights. Notaries public have disgraced their seals and prostituted their office by the making of false jurats. And even the probate courts have been converted into mere machines for the production of ready-made administrators, regardless of the domicile of the parties or the locus or ownership of the rights involved.

It naturally follows that claims established in this manner will not bear investigation. In the case of mere rights, without any accompanying certificate, there is no occasion for investigation until an application is made to locate the right upon a specific tract of land. The location may fail—it frequently does—but in the meantime the locator, who may have purchased the right in good faith, has at least some color of title, and if he should remove the timber from the land, he would be liable only as an innocent trespasser and could be made to pay only the stumpage value of the timber. The land would be denuded of its timber and yet not be cleared land suitable for cultivation, and, considering the cost of the investigation, the result would be a net loss to the Government.

So many affidavits have proved false, so many forgeries have been made manifest, and so many invalid judgments rendered to "quiet title," that the Government must exercise every care possible for the protection of its interests.

Moreover, in addition to protecting itself, it is the duty of the Government to protect, as far as possible, the owners of the rights, because in many instances the identity of the real beneficiary is the only question involved.

While the difficulties encountered upon the location of rights not represented by scrip or warrants are not usually attendant upon the location of certificates which have been previously issued, it does not follow that the law is more easily administered when the right to locate is represented by a written certificate. Indeed, there is little difference whether the right is represented by a certificate or not. In the case of mere rights the difficulty is not encountered until the location is attempted, while in the case of certificates the difficulty is encountered before the warrant or scrip is issued.

In the case of surveyor-general scrip, under the act of June 2, 1858, where, as the name indicates, the right is represented by a certificate issued by the surveyor-general, most of the land claims which formed the basis of the scrip were confirmed by laws enacted prior to 1825, and many as early as 1807, while the act which granted scrip for such of these claims as could not be satisfied in place was not passed until 1858. Consequently, most of the original claimants were dead before the scrip act was passed. Their heirs or assigns had little or no knowledge of the conditions, and made no effort to obtain the benefits of the act. Notwithstanding this, hundreds of thousands of acres of the scrip were issued and delivered to persons who secured their standing as legal representatives of the confirmees through so-called probate proceedings. Of the half million and more acres of scrip so issued, it may be safely said that not one-tenth of it reached the beneficiaries intended by the law. Men of straw were appointed administrators, who either sold the claim for a nominal sum, sufficient only to defray the expenses of the probate proceedings, or who secured the scrip and sold it for its market value, converting the proceeds to their own use, no account whatever being rendered to the court, and none ever being demanded. Men of fine abilities devoted their energies to the acquisition of this scrip. The rulings of the Land Department were evaded by one means or another, and the special service of the General Land Office being then in its infancy, or not yet even in existence, the illegal traffic continued. As illustrative of the conditions and the attitude of the scrip men, I may refer to a letter written many years ago, which accidentally fell into my hands some years afterwards. In that letter the writer (a scrip dealer) informed his partner that "eternal vigilance is the price of scrip."

It was not until quite recently, when the special service of the Land Department became thoroughly effective, that an end was put to this practice. It is now more or less an open question whether the Government is liable to the real beneficiaries for the value of this scrip.

Under the forest lieu act of 1897, the right to exchange depended solely upon the ownership of land in a forest reserve. Consequently, no stone was left unturned to obtain advance information as to the creation of these reserves, in order that lands to be included therein might be acquired before the reservation became effective. Officials were bribed to furnish this information, after which every possible effort was made to acquire a title that could be exchanged, and to this end frauds were committed upon the States to induce the selection and sale of such lands.

The administration of laws which entailed such close scrutiny in the office, and such thorough investigation in the field, is necessarily expensive. It becomes necessary for the clerks employed to acquire an intimate knowledge of the laws of all the public-land States affecting in any manner the title to real estate, and the means resorted to by some of the scrip men render it necessary for the inspectors to master almost every phase of criminal law. Considering the value of the land surrendered, it would have been much less expensive if the Government had purchased the base lands for cash.

It is but proper to state that the difficulties encountered in connection with the issue and location of scrip of the classes indicated above are not usually attendant upon the indemnity selections made by railroads and the various States, owing to the fact that the Government deals directly with the railroad or the State, as the case may be, and the quantity of indemnity may be readily determined simply by a proper method of bookkeeping. Therefore, in such cases, the only question involved is the character of the lands to be located. This, of course, at times, necessitates investigations in the field to determine the character of such lands.

The quantity of indemnity to which the State is entitled under its school grant can, in no cases, be determined until all of the land in the State has been surveyed, because, until the survey is executed, it is impossible to ascertain whether or not the right of the State to the particular sections granted has been defeated. This right, of course, is affected from time to time by the creation of national forests and other reservations, and also by the settlement, by qualified persons, of unsurveyed lands. It may be said, in this connection, that, during the past fifteen years, some 6,000,000 acres of indemnity were certified to the various States, of which amount, 1,000,000 was certified during the past year.

I shall state, for the information of the commission, that the scrip rights acquired during the operation of the act of June 4, 1897, approximate 3,000,000 acres; of this quantity it is estimated that the outstanding rights, which were protected by the repeal of the act of 1897, will approximate 25,000 acres. Claims based upon deeds of reconveyance to the United States, where no selections were made prior to, and which were not protected by, the repeal by the act of 1905, are supposed to approximate 40,000 acres.

There are outstanding comparatively few surveyor-general and Supreme Court certificates, but possibly more than 2,000,000 acres are involved in the outstanding military bounty land warrants. These certificates and warrants, however, can hardly be classed as scrip at this time, because, under recent rulings of the Land Department, they may be used only in lieu of cash in the payment for lands entered under the various general laws, at $1.25 per acre; that is to say, these certificates and warrants may not be located as scrip usually is located.

Of the several kinds of personal scrip which issued under special acts of Congress there are only a few rights outstanding, some of which, however, are very valuable, owing to the fact that little limitation is imposed upon their location. Valentine and Porterfield scrip are included in this class.

Soldiers' additional homestead rights constitute, perhaps, the most important class of scrip which is outstanding. Its importance is due to the fact that it is assignable and may be located by the assignee upon any lands subject to homestead entry, no settlement, residence, or actual improvement being required. Speaking generally, the right exists where the qualified soldier made a homestead entry prior to June 22, 1874, for less than 160 acres, the amount of the additional right being the difference between the quantity originally entered by the soldier and 160 acres. The total quantity of outstanding rights, therefore, can be determined only by first ascertaining the number of entries and the quantities of land embraced therein, which were made by such soldiers prior to 1874, and, owing to the fact that many entries were made before the military service was rendered, the entry papers themselves contain no evidence whatever connecting the entryman with the subsequent soldier. This fact constitutes one of the important features of the right, and also renders the law exceedingly difficult of administration.

In the limited time allotted it is impossible to consider every phase of this subject; but one point remains which should not be passed unnoticed. The parties intended to be benefited by the scrip laws seldom if ever realize the full value of the rights granted. To use a trite figure, the men who owned the claim constituting the basis for the right, assisted by the Government, sow the seed, but the middlemen reap the harvest.

Many owners of scrip have no sense of its value, and I have heard men boast of having bought a soldier's additional right at less than one-tenth of its value. I have even heard of the purchase of a 160-acre bounty-land warrant for the sum of 50 cents. True, some of the rights are expressly made nonassignable, but even in those cases the law is evaded by the appointment of attorneys in fact, with power to locate the right and sell the land.

It will thus be seen that where scrip rights are involved, if the Government would protect its rights and those of the individuals intended to be benefited, it too must exercise eternal vigilance.

LAND CLASSIFICATION—SHOULD SURFACE BE SEPARATED?

By Fred Dennett,
Commissioner of General Land Office.

When the position of geographer of the United States, under the Department of the Treasury, was established by the act of May 20, 1785, the officer who was appointed was confronted with the proposition of, first, arranging the lands in blocks and, secondly, of securing a purchaser for them when so arranged and made capable of description. The acres were so numerous, and money needed so seriously for the debts of the United States, that it was not so much a matter of particularity as to what was sold as to finding some one who would make a bid for what was offered. There were some 1,422,000,000 acres on the market, and when an association of individuals offered $1,000,000 for as many acres in what is now the State of Ohio, they were welcomed and the deed willingly handed them.

Even in the early times, however, it was understood that there should be some knowledge obtained as to what the United States had in its public domain, and by the act of May 18, 1796, provision was made that "every surveyor shall note in his field book the true situation of all minerals, salt licks, salt springs, and mill seats which shall come to his knowledge, all water courses over which the lines he runs shall pass, and also the quality of the land." Under the law at that time the returns were filed with the surveyor-general, but by later enactment the descriptive notes, as they are called, were to be filed in the office of the register and receiver. By various subsequent enactments geological surveys of the public domain were authorized, and such surveys were made of the States of Michigan, Wisconsin, Iowa, and Nebraska and other Western Territories, but section 2406, Revised Statutes, provided that there should be no further geological surveys unless thereafter authorized by law. By the act of March 3, 1879, the office of Director of the Geological Survey of the Interior Department was established. The act provided that this officer should have direction of the geological survey and the classification of the public lands, the examination of the geological structure, mineral resources, and products of the national domain. It was held, however, by the first director that this did not give the Director of the Geological Survey the duty of classifying the public lands, to the extinction of the direction given to surveyors and their returns. In this judgment he probably was confirmed by the fact that only $100,000 was authorized for the expenses of the survey.

The records of the General Land Office show that at one time where lands were returned by the surveyor-general as mineral the same were withdrawn from all forms of disposal except under the mineral laws. This sort of withdrawal met with strenuous opposition by those desirous of securing title to lands which they alleged to be non-mineral in character, but so withdrawn, and the withdrawals were revoked by Secretary Schurz in 1880 and the practice of making suspensions, based upon the reports of deputy surveyors, discontinued.

There is no doubt but that the classification so made was inaccurate. The deputy surveyor is not a mineralogist or geologist and runs lines which are a mile apart, works for the completion of his contract and not for the exploiting of the character of the country. Local influences would be very strong and might exercise a power over him which would be to the detriment of the general service. The rough classifications were, of course, of use, but the tendency at first was to give them greater recognition than they deserved. In fact, the rough return of the deputy surveyor was contended up to within the last eighteen months as being binding on the department in a lieu selection for lands classed as agricultural, when it was a known fact that coal existed thereon, the deposits being discovered at a time subsequent to classification. It is, however, held by the department that these returns can be overcome by evidence; and to hold otherwise would be fatal.

It is a curious circumstance that the method of doing that which was recognized as a necessity when the lands were so numerous has not been improved or kept abreast of the times and pursued with greater particularity when the lands have become comparatively scarce and the necessity for classification therefore the greater.

The General Land Office issues each year a list of the "Unappropriated Public Domain of the United States," which is based upon the returns of the descriptive notes of surveyors very often made years before the publication of this document. The lands left are the "culls" and the classification, which was made of lands before they were picked over, does not fit. In some instances climatic conditions seem to have changed and at least the basic principles upon which the lands were classified are not now as they were. Methods of dry farming have made a change in the classification of that which we would have called arid lands at one time. The "brief description and character," so called, in this list, is inaccurate and misleading and there is not an intelligent understanding of that which the United States has left to offer. It was generally supposed eighteen months ago that there were but few areas left suitable for home building. During the past fiscal year, however, there have been 88,000 entries made under the homestead law and 23,000 commutation proofs accepted, a goodly percentage of which must have been perfected since that time, thus showing that the information at hand was not as perfect as a country as modern as the United States should have.

There come to the Land Office from various parts of this country and from abroad many requests for information as to our domain and the character of the land which is left. There is returned the list referred to above with a feeling that it furnishes very little that can authentically be relied upon, and the question naturally arises as to whether or not the General Land Office should not have authentic facts which would guide a would-be settler in his search for a home.

The benefits of a thorough classification would be vast even though that classification might not be conclusive for or against the government. It would give to Congress intelligent information of how to obtain the best results from the disposal of the remaining public lands of the United States; it would furnish the executive officers and their agents with a guide in attempting to follow the mandates of the legislative body; it would at least serve as a caveat to thwart those who seek to obtain unlawfully that which there are many desirous of obtaining with a full compliance with the statutes; it would be a warning that difficulties would be encountered in the acquisition of lands if sought under a law which did not embrace the lands, as classified; it would assist in the determination as to what should pass under applications under the timber and stone act. Complaints have been received from various mining districts to the effect that timber and stone applicants seek to gain possession of lands which are really mineral in character. It has been the policy of the General Land Office to watch these as carefully as possible, but the only methods of detecting the application at present are, one, by a contest instituted by an individual, and, two, after protest made, by an examination by an agent, and for the latter work there are not agents enough, but it is an undisputed fact that there are many people who would be willing to gamble $400 for 160 acres of land in the vicinity of a mineralized territory on the off-chance that at some time minerals might be found therein.

We have yet to know what the effect of the instructions recently issued concerning the purchase of timber and stone lands will be upon this situation.

Would it not be of great value to Congress, could it have submitted classified list of its lands, upon which water can be brought in some future time, to make more homes to the quarter section, so that it could consider the advisability of legislation to preserve the lands for such purpose? One of many similar instances suggests itself wherein the claimant openly asserted that he had not grown any crop upon the land he claimed as a home, and that none could ever be grown without irrigation, but he wanted the land because some day the Government would, he thought, irrigate it. When such time comes, as it will come, the object of the act of 1902 will be, to that extent, defeated. There will be but one home where Congress intended more should be built. Had the area of coal lands been ascertained, the executive officers would not be offering a record of 474,834.54 acres patented under the coal land laws, and many times that number of coal lands in private possession, obtained from the public domain. Had the timbered domain been accurately ascertained, with the character of the lands, the abuse of the commutation clause of the homestead laws, as shown in these regions, might have been stopped by Congress preventing the application of this clause to such of the public domain as presented a value in trees and not a present value in land. Laws might possibly have been enacted to fit classified areas and the lands therein, and not one law to attempt to fit all the domain alike. It has been experienced by the agents in the field that sometimes it is a severe strain on a law to make it fit all conditions, which were not appreciated or known at the time the law was passed, being enacted to cover a status known at the time and having to meet new conditions to which it was not suited, as the latter have arisen.

Out of the original 1,421,777,280 acres of the public domain, we have disposed of 1,034,903,493, leaving some 386,873,787 acres to satisfy hungry land seekers who clamor for homes. These totals exclude the estimated 368,103,680 acres in Alaska. The lands so left are naturally the poorest. Fewer acres to give away, and a greater demand for them.

In October of this year there were 4,000 160-acre farms thrown open for home seekers in the Rosebud Reservation in South Dakota. They were not free homes. There was an indebtedness to the Indians of $6 on every acre. For those 4,000 homes there were 114,769 applicants, nearly 30 people who wanted to everyone who will obtain a chance to build a home.

A great deal of the prosperity of the United States and happiness of its citizens has been due to the fact that there has been room for expansion and a place for every man. There is but one conclusion to draw from this object lesson, and that is that the few lands which are left must be put to their greatest possible use. The surface should afford a home, though tunnels honeycomb the earth beneath.

There are vast areas of land on the Pacific Coast which carry great values in their trees. Much of these areas have been sold for their tree values alone, but the soil has been purchased with the firs and spruce. Some day the sawmills will reach them and the lands will become what are called "logged-off lands." When the purchaser acquired them there was no consideration given to the value, either present or prospective, of the soil. The lands were cruised and the moneys paid for the board measure of lumber. The lands passed with the deed. There is no one living on the lands so sold. But every once and again in the woods the traveler unexpectedly sees meadow land, a farm house, and growing crops. The farmer there will have small chance of securing neighbors, even after the trees have disappeared, for the logged-off lands will be held at a price and there will not be a free home offering an opportunity for some one who would build up values on the land to take the place of the trees it has lost. Of course, ultimately the land will be used, but not as soon as it would have been if the land were open to settlement after the trees had been cut off, and a free home could have been acquired by one who has not the price to purchase the lands, but who has the brawn and willingness to force a living from the lands if he could have secured them from the public domain.

Of course there are men who like solitude. Men there are who rejoice in the fact that the "last homesteader" is moving out, for then there will be no neighbors. But it need not be argued that the greatest good is not attained where there do not live men enough to build the trails, to make the roads, and continue the work of wresting from nature the greatest returns she is willing to give.

The evils of the present practice of giving to an applicant that which he does not ostensibly seek are shown more evidently in the workings of the coal land laws, where surface rights go with the application for the coal. The question of the operation of the present law will be discussed at a later moment, and its inadequacies presented. The homesteader seeks for the farm land only. He swears that he knows of no mineral deposits within the boundaries of his farm. One instance, a sample of many, where a claimant has lived upon his farm for twenty-three years. He has slept upon his rights, in so far as filing is concerned—but that could be cured—only to find at the time of wishing to perfect proof, that below the surface there is a deposit of coal which will prevent the issuance of his patent, under the law, as it now stands. He did not and does not want the coal. He wants his home. But the law says that he must take even to the center of the earth, and can not acquire that, if workable coal be found beneath his tillable land. We are at an impasse and yet the same land could practically be utilized for the two purposes—the mine and the home.

Alaska, with its 368,021,509 remaining acres of public lands, has not been prominently brought forward in this paper. The difficulties which will present themselves in the intelligent treatment of the lands of Alaska are before us. The experience of the past should guide. We have already learned that Alaska is not a country of barren hills and waste valleys, but that there are there fruitful vales and pasture grounds. The situation in that district must be met at the outset.

These thoughts are presented for the consideration of the committee; not intended so much to be argumentative as to offer matters which are, it is hoped, worthy of attention.

PRECIOUS MINERALS ON LANDS OF THE UNITED STATES.

By **Edward C. Finney**,
General Land Office.

The history of the mining of precious metals in the United States, in so far as related to existing laws, may be said to have begun with the discovery of gold in California in 1849 and the influx of treasure seekers to remote localities where, because of the nonexistence of federal and state laws, the miners were of necessity compelled to devise and adopt rules governing the location and possession of mining claims. The rules adopted by the early miners, as stated by Justice Field—

> All recognized discovery, followed by appropriation as the foundation of the possessor's title * * * and they were so framed as to secure to all comers, within practical limits, absolute equality of right and privilege in working the mines.

The mining laws of the United States, which have been in force with slight modifications since 1866 and 1872, were drafted by men who not only represented the mining States in Congress but who had actual experience in mining operations. To a considerable extent these laws recognized and adopted the customs and local regulations previously adopted by miners on the ground, especially with reference to placer-mining claims. The law with reference to lode claims was probably, as suggested by Mr. Lindley in his work on mines, based upon the customs in vogue among the lead miners of Derbyshire, requiring location to be made upon a discovery upon the top or apex of the vein and permitting the locator to follow the vein on its dip, whether within or without the surface area of his location, to the intersection of the vein with vertical planes drawn downward through the parallel end lines of the location. With vein or lode claims the principal thing sought and to which the laws have been specifically directed is the vein itself, the right to acquire sufficient surface for the convenient working and development of the vein being accorded by the law. Lodes or veins were not placed by nature in straight lines or at regular intervals, and any change in existing laws should be framed to meet actual conditions and not theoretical ones.

Under existing laws of the United States, one who has discovered the apex of a vein or lode may locate a claim 1,500 feet in length along the presumed course of such vein with surface ground not exceeding 300 feet in width on each side of the line of the lode. The discoverer of a placer deposit (and the term placer has been construed by the

Interior Department and by the courts to include not only such precious minerals as placer gold but deposits like sapphires, sheet asphaltum, building stone, oil, and gas) is authorized by the law to locate 20 acres of ground surrounding his discovery, the location conforming as nearly as practicable with the United States system of public-land surveys. From two to eight individuals may, however, combine in making a location which shall not exceed in the aggregate an area of more than 20 acres for each locator, thus permitting eight locators to locate and obtain patent for 160 acres of placer ground upon one discovery and the expenditure of $500 in development and improvement for the entire claim. The law, however, does not limit the number of separate lode or placer locations which may be made by individuals or associations.

These laws were designed to and have had the effect of promoting the development of the mineral resources of the United States. The history of mining operations in newer fields being usually that placer deposits are discovered and worked first because this class of deposits can be mined more cheaply and readily by the individual miner than can minerals found in rock in place; thus in Colorado, California, and latterly in Alaska, the placer deposits were discovered and developed first, and very properly the existing laws have been exceedingly liberal in the matter of the rights of miners with respect thereto. Later, as the regions become more thickly populated and capital seeks investment in the field, the lode deposits are developed. The vast amounts of gold taken from mines of California and Alaska, the production in the last-named district having increased from about $1,000,000 in 1880 to over $19,000,000 in 1907, have largely come from placer deposits on the public domain or from lands acquired under the placer-mining laws. As an instance of the enormous wealth found in veins or lodes, may be cited the Independence mine in the Cripple Creek district in Colorado, reported to have been sold a few years ago to an English syndicate for $15,000,000, the Camp Bird mine in the Creede mining district in Colorado, and the silver mines of the Coeur d'Alenes in Idaho. Among the profitable mines of low-grade ore may be mentioned the Treadwell mine in Alaska and the Homestake mine in the Black Hills of South Dakota.

Improved methods of mining and in the reduction of the ores have already increased and will continue in the future to increase enormously the output of mineral wealth from low-grade ores. In the mineral regions prospectors are constantly searching for new deposits, and as a result discoveries are frequently made in localities where the existence of mineral was undreamed of. In fact, for many years stock men, prospectors, and the like passed over the Cripple Creek district without suspicion of the vast mineral wealth beneath their feet, but each new discovery widens the field and promotes search for the precious substances. After the discoveries of gold in the Tonopah and Goldfield districts in Nevada, the country far and near, even far north of Reno, looked as though colonies of gigantic gophers had been delving in the hillsides. Up to June 30, 1908, 1,269,614 acres have been patented under the mining laws.

However, during recent years, owing to the increasing value of timber and of water and water powers, there has been a temptation, to which many of the unscrupulous have succumbed, to seek to acquire title to nonmineral lands containing a growth of valuable timber, or to control the course of a stream or a waterfall by means of alleged mineral discoveries and locations, especially under the placer-mining law. This law, as heretofore indicated, is exceedingly liberal, the lands being disposed of at $2.50 per acre. It is an expeditious and easy way of obtaining title to the land. In one instance attempt was made to acquire title under the placer-mining laws to a tract of land 5 miles long and about 50 feet in width lying upon either side of a stream of water, the obvious purpose being to control the water, not to secure minerals. In a case that I investigated in California, one individual and his associates had more than 250,000 acres of lands within and about a national forest, covered with alleged placer-mining locations, each location being made by eight persons and notice of the location recorded upon the county records. Thereafter most of the claims were conveyed to the instigator of the scheme or to a corporation in which he was interested.

I found that these locations were, to say the least, impartially made, as they covered streams, valleys, mountain sides, and mountain tops. Nearly all of the claims were covered with a valuable growth of standing timber. In many instances I could find no evidence of any work whatever having been performed upon the locations; in other cases, the improvements consisted of log cabins erected from timber cut upon the lands. Most of the locations failed upon careful examination to disclose any placer mineral; and in not one instance were mining operations being carried on. One of these claims located along the course of a stream failed to disclose a single color of placer gold, but was found to be exceedingly valuable, because of the fall of the stream and the amount of water therein, for a power-plant site. When this claim was attacked, the owner failed to put in an appearance, and the claim was canceled on default. This case indicates the extent to which fraudulent locations may be made under existing laws. Many other instances have come to my attention where attempts have been made to acquire title to this class of lands under the placer-mining laws, and the location of mining claims has often been resorted to as a means of obtaining and holding possession of ground for townsite, business, or other purposes. It must be borne in mind that under existing laws one who has made a valid discovery and location of a mining claim is entitled to the exclusive enjoyment and possession of the land and is not required to apply for a patent or pay the United States for the land within any specified period. Thus fraudulent locations have the effect of depriving both the United States and its citizens of the use and possession of the ground covered thereby, and such claims are only set aside after long and expensive proceedings before the department or in the courts. In other cases, where the lands do contain placer deposits, the applicants, not being required by existing law to pay for the lands and make entry within any specific time, work out the deposits and abandon the lands, leaving to the United States the worthless residue. Another defect is that under existing laws notices of location are not required to be recorded in the local land offices nor in the General Land Office. They are recorded, if at all, either with the local mining district or county recorder, and the officers of the United States charged with supervision over the public lands have no positive knowledge as to the number or extent of such existing locations. With reference to the annual assessment work required by section 2324, Revised Statutes, to be performed upon mining claims, there is no penalty prescribed save the liability to relocation by others, nor is proof of the performance of this work required by law to be filed in the Land Department. The result is that the department, having no jurisdiction over the matter of annual assessment work, is unable to secure the enforcement of the evident purpose of the law that not less than $100 must be annually expended in development of each mineral location or to declare invalid locations based upon actual discoveries of valuable minerals, but upon which this assessment work is not performed.

To conclude, it is suggested that because of change in conditions, both with respect to the minerals themselves and the other products or appurtenances of the soil, the fact that there is no law requiring entry to be made within a definite period, that the maximum area of placer claims is too large, and because the law does not require the record of location notices and assessment work to be made in the Land Department there is an apparent tendency at present to attempt to acquire a control of timber land, waters, and power sites on nonmineral lands, through alleged placer locations, to monopolize the same, and to maintain possession and continue to use the same without payment to the United States of the amounts contemplated by law within a reasonable time.

PUBLIC LANDS CONTAINING DEPOSITS OF COAL.

By T. J. Butler,
General Land Office.

The act of March 3, 1873, provides for the disposal of the public lands of the United States containing valuable deposits of coal. Under its provisions every person above the age of 21 years, who is a citizen of the United States, or who has declared his intention to become such, or any association of persons each member of which is a citizen of the United States above the age of 21 years, or has declared the intention to become such, has a right to enter any quantity of vacant coal lands of the United States not otherwise appropriated or reserved, not exceeding 160 acres to such individual or 320 acres to such association of persons, upon payment of not less than $10 per acre for such lands where the same are situate more than 15 miles from any completed railroad, and not less than $20 per acre for such coal lands as shall be within 15 miles of any completed railroad, or if such association consists of not less than four persons, and shall have expended not less than $5,000 in the development of the mine, it may enter a maximum of 640 acres.

Under the present holding of the department, and of the courts, only lands that contain a deposit of coal possessing commercial value may be entered under said laws. The theory of the law is that the prospective entrymen will open up a mine such as will demonstrate the value of the land as a coal proposition. No means has been provided by the Government for ascertaining whether or not each particular legal subdivision contains a valuable deposit of coal, further than the geological deductions from known facts, such as outcrops, or mines upon veins in the vicinity of the particular tract in question, and, as in many instances, lands which contain valuable deposits of coal are valuable for agricultural purposes or for the timber they contain, great confusion has resulted in the classification of such lands.

Less than 500,000 acres of the public lands have been disposed of by the Government as coal lands and patents issued under the coal-land laws. It will be admitted that the area disposed of since the enactment of the law in 1873 is very small as compared to the entire area of public land containing valuable deposits of coal. This results from other reasons as well as from the difficulty in the classification of the lands, and is due, in a large measure, to the fact that under the present law, only 160 acres of land may be acquired from the Government by the individual, while the maximum for an association of not less than four persons is 640 acres. It is conceded that the area allowed to be acquired by entry is, as a rule, too small to justify the great expenditure required in the opening up and successful development and operation of coal mines. Those possessed of the means of developing lands of this character would not be warranted in investing the sums that would be required in such development, and the production of coal, and to place it upon the market unless they were permitted to acquire a sufficient quantity of lands as a basis of their operation to render their investment a permanent one. As a result the tendency has been for persons and associations, who make entries and acquire patents to lands under the coal-land laws, to sell the same to corporations or large companies who develop them more with a view to the financial prosperity of the operators than to the interest of the public, and as the process of equipping the mine is expensive, it would be an impracticable and unwise investment if the area permitted to be entered were so limited as to make exhaustion within a short time certain.

Frequently coal deposits appear upon the surface of the land, which, if opened up by excavation into the side of the mountain where they appear, are, at a short distance from the surface, valuable deposits, while at the surface, and for a considerable distance beneath it, by reason of disintegration, the coal is of little value; and the individual who is led by the appearance of the coal on the surface to make entry of the land on which it appears finds that he has reached the limit of the land embraced within his entry before he has removed the disintegrated and valueless coal and reached the deposit that is of actual value.

Under the present law, if the land contains a valuable deposit of coal, which may be found at a great depth beneath the surface, and at the same time is of great value for agricultural purposes, or for the timber it contains, the fact that it contains such a deposit of coal prevents the home seeker from acquiring the surface as a home, or the investor from developing the timber product. In sections of the public-land States there are vast areas, frequently several townships in extent, which are underlaid with valuable deposits of coal, and the surface of which is fertile and productive and of great value for agricultural purposes. A large part of these lands has been settled by actual settlers in good faith who have constructed valuable improvements, with the purpose of establishing permanent homes, but it having become known before title was earned by the settler that such coal deposits exist upon the land, the Government has been compelled to cancel these entries at great loss and injustice to the settlers, and with no gain to the Government or anyone else; or, if patent issued before the deposit became known, title to the coal deposits as well as to the surface of the land was, by the issuance of the patent, divested from the Government and vested in an individual who found it impracticable to develop the resources which his land contained. As a result, the coal field either remains undeveloped or an intended monopoly steps in and acquires from the individuals the coal rights covering the entire field, which rarely results in a development for the best interests of the public.

It also frequently occurs that lands contain such a deposit of coal as may be profitably mined, and at the same time are of greater value for agricultural purposes. Under the present law, it is not necessary that the coal deposit be of sufficient quantity and merchantable quality to render the land more valuable for coal as a present fact than for other purposes, in order to render it not subject to entry under the homestead or other agricultural laws, but it is sufficient to prevent agricultural entry if the land contains a deposit of coal possessing a commercial value. The Land Department now finds itself confronted with a situation something like this: There are now pending before the General Land Office approximately 5,000 homestead entries in support of which final proof has been submitted, and it conservatively may be estimated that an equal number of homestead entries where proof has not been made embrace lands that have been reported by the United States Geological Survey as coal lands.

As instances of this character, the coal fields of North Dakota, which to a great extent underlie a practically level or gently undulating fertile plain, and the Raton coal field in northern New Mexico may be cited. In the North Dakota fields there are many localities where mines have been opened up showing a vein of good lignite coal 6 or 8 or 10 feet in thickness. These mines frequently are located on lands 8 or 10 or as far as 16 miles from the Missouri River, and the veins of coal have not been opened between such mine and the river, but the government geologists, who have made examinations of these lands, have been compelled to classify all the lands between the river and such coal mines as coal lands for the reason that the same vein of coal, or what appears to be the same vein of coal, is visible in the banks of the river. This intervening space of from 4 or 5 to 16 miles in width is almost entirely occupied by settlers who have made entry for the land as homesteads.

Many of these homesteaders have resided upon their farms for from five to seven years; have built comfortable houses and other improvements, in some instances of a value of from $1,500 to $2,000, and cases have come under my notice where improvements valued at $3,000 and even more have been made by such homestead entrymen, with a view to obtaining title to the lands from the Government under the homestead law. The situation in the Raton coal field is quite similar. In that field the deposit of coal consists of several veins varying in thickness from a few inches to approximately 7 feet. The coal is of excellent quality, and is said to be one of the best steam-producing coals that has been discovered in the United States. These deposits are found in blanket veins, which outcrop in the side of the mountain at approximately 1,000 feet below the top of the mountain. The top of the mountain is a flat mesa from 1 to 5 or 6 miles wide, and is covered with a growth of grass sufficient to render it valuable for grazing purposes, or where under cultivation abundant crops are produced. This mesa has been taken up by homesteaders, who have established comfortable homes and a prosperous and substantial community differing from the coal fields of North Dakota, in that patent has issued, and these homesteaders have practically all received title to their lands.

While the issuance of patents protects the interests of the individual in his improvements upon the land and his right to the use of the land and the coal it contains unless fraud is shown, still the fact remains that the Government has divested itself of all title to, interest in, or control over the valuable deposits of coal which underlie the patented land. In neither of these instances can the settler be charged with actual knowledge of the coal character of the lands which he has selected. There are no outward appearances upon his land or in the immediate vicinity thereof that would charge one not a geologist, or without considerable acquaintance with geological formations, with knowledge of the presence of coal upon such lands. The settlers have gone upon the land innocently without intention of violating the law, in pursuance of the natural home-making instincts, and after having performed all that the Government requires of them under the homestead law, the Government has found itself unable to protect them in their rights to their improvements and the use of the surface of the land, as there is no provision of law whereby title to the surface of the land may be granted without granting title to all that lies beneath the surface.

Under the present land laws no provision is made whereby the Government may develop the natural resources of its own land. In order to render these resources available the Government must divest itself absolutely of all title to the land and the deposits of coal which it may contain, nor has the Government any power under which it may, after it has divested itself of the title to the land, prevent the lands from being brought under the control of a monopoly, and either withheld from development or being developed in a wasteful manner. It thus happens that interests which own lands upon which are operating coal mines in one section of the country acquire control of other coal fields and prevent the development thereof, because they deem it of financial benefit to themselves that the coal from this other field should not be placed upon the market and made available for public use. It, of course, is unfair and unjust to the community where such undeveloped coal fields lie to be compelled to purchase the product of a distant field and pay transportation expenses.

Besides all these defects in the law as it now stands there is what, from the standpoint of public policy, is greater and of more importance than any or all of them—that is, the absolute lack of provision whereby the Government can conserve its coal resources or in any manner regulate their development. Under the present law, when the Government parts with title to the land, the private parties may conduct their operations in such manner as they see fit, and may entirely exhaust the deposit if it seems best for their financial interest that they do so. They may operate their mines in such manner as to take out only the heart of the vein, which is of the very best quality, while large quantities of coal possessing utility are either permitted to remain in the ground or to waste upon the dump at the mine opening. It is a fact of common knowledge, and it is necessarily so, that under the present law this great natural resource is simply a subject of speculation, dependent upon the present exigency of opportunity for financial gain and with no concern for the future.

The development and production of coal is conducted entirely without concern as to the coal supply for the future. The result has been that in many sections of the country the coal supply already is becoming depleted, and in some cases has been exhausted and the mines abandoned. In this connection, when I say the supply has become depleted or exhausted, I do not mean as to the physical presence of the coal, but as a profitable investment the operation of the mines is not sufficient inducement to withdraw the necessary capital from other channels of trade. Under the present law, if an applicant is qualified to make a coal entry and acts in good faith and complies with the requirements of the law, he can not be refused patent, and when patent issues, under such circumstances, the Government divests itself absolutely of further control over the coal deposit or the development thereof. No matter what waste may be committed, nor to what extent the public may be deprived of the use of this great resource, the Government can not, except under its police power, interfere with the right of dominion over his property exercised by the individual.

THE DESERT LAND ACT.

By W. B. Pugh,
General Land Office.

It is difficult if not impossible to conceive that Congress, when it framed and enacted the acts of March 3, 1877, and March 3, 1891, which contain what we commonly call the law of desert-land entries, did not have in contemplation the beneficent results incident to a complete and permanent reclamation of the arid public lands as distinguished from a partial and temporary achievement in that direction. And I think it will, as it must, be conceded that such was the object and the hope of the lawmakers, for, as reformation is never of any value save as it is effectual and durable, so would reclamation of waste and desert areas be useless and unprofitable if subjugation is to be only for a time, after which the desert is to return with all its incidents. Temporary reclamation is nothing but a casual suspension of natural conditions, and without continuing means of and provision for irrigation a reclaimed desert would soon relapse into its former state of aridity and barrenness.

The law intends, and expressly demands, that as a condition precedent to the acquisition of title to desert lands, the individual who seeks the benefit of its license shall perform and prove actual and absolute reclamation of the whole area of the entered land. There is no qualification, in the language of the law, as to the extent or degree of successful achievement, but a plain and unequivocal requirement of full and complete redemption. The letter of the law does not authorize any disposition thereunder of one solitary acre of unreclaimed lands, but the Interior Department, charged with administration, has very properly construed its provisions in such manner and to such effect that, where it is satisfactorily shown that there are included scattered areas too high or too stony to admit of successful and practicable irrigation, failure to carry water onto those areas will not defeat an application for patent. By way of taking some security for the future the law has been held to require that as a means to permanent irrigation the entryman shall possess, in his own right and by an absolute title, the right to the use of water sufficient for the irrigation of all of the irrigable land included in his entry; and, by way of providing for irrefragable and indisputable evidence that the grasp of the desert has been broken and cast off, it is required that at the end of four years the entryman shall prove that he has successfully cultivated at least one-eighth part of the land he has undertaken to redeem.

Having laid this premise as to the spirit and the purpose of the law, as evidenced by the several specific provisions or constructive requirements thereof to which I have alluded, I shall now make a few suggestions as to the practical workings of the law as I have had opportunity to observe them in the field.

First. It is manifest that, apart from those evils to which the operation of every public-land law is subject, which have their origin in craft and cunning and guile, and which tend to defeat the design of the law, the administration of the desert-land law is subject to abuses which may be deemed special and peculiar. In the short space allotted to me I can only direct attention to two or three of the principal of these abuses. What seems to be a very serious evil, and one commonly met with in practice, may be ascribed to the failure of the law itself to fix and prescribe any minimum of irrigable and irrigated area, out of a total area entered, which will entitle the entryman to patent. As I have previously pointed out, the department, considering that Congress must have known and had in mind when it enacted this law that nearly every desert-land entry would embrace some small spots or parcels of ground which could not be irrigated without resort to expenditure greater than any possible value those particular parcels would possess in a reclaimed condition, has so administered the law as not to require proof of the irrigation of such small parcels. As to such included areas the only requirement of proof is that it shall be shown that reclamation is impracticable. But the department has not prescribed, and can not establish, any engineering standard by which to determine the practicability or impracticability of irrigation to which resort may be had in all cases, and must manifestly accept the statement of the claimant and his proof witnesses concerning such an alleged condition; and it is more or less obvious that the determination of what is and what is not practicable in irrigation is, as it must be, left largely to the conclusion of the claimant and those who testify in support of his claim.

The proof usually submitted in support of such a contention or conclusion is wholly nonexpert and unprofessional and is generally extremely simple and indeterminate in character and probative tendency. As a result of this want of fixed limitation and in the absence of any standard by which to measure practicability of irrigation, desert-land entries for 320 acres of land very frequently pass to patent upon proof showing reclamation of only 40 or 45 acres; and in passing it may be suggested that even this slight modicum of achievement is often of doubtful value. While serving in the field I have often had my attention directed to desert-land entries on which patents had been granted of the lands of which only a small portion had been irrigated. It required only a casual examination to create the conviction that the expenditure of some very small sum of money in addition to what had been expended, or the exercise of some greater intelligence or care in the choice of a location for the diversion dam or reservoir, would have resulted in an important increase in the irrigated area. The impression created in my mind, as the result of what I witnessed of the operation of the desert-land law, is that it is too frequently the case that the entrymen of such lands desire to secure them only for pasture for cattle, for which purpose they would provide a sufficient growth of grass without irrigation, and that reclamation is only a fiction, or perfunctory sort of process, necessarily preceding application for the legal title. It is also true that the entryman, when he comes to determine what portion of the entered lands it is practicable to irrigate, does not always have in mind the test of practicability described by the department, to which I have previously alluded, but rather refers to the state of his purse, or his willingness to make the expenditure necessary for reclamation of a larger area.

Second. The water rights relied upon are too often so precarious, or so utterly without merit, as to hardly deserve the title. Very frequently do they depend upon mere surface-water drainage, accumulated in or by a dry draw, coulee, or arroyo and conserved in a reservoir created by constructing a dam across the coulee at the place of ultimate impounding.

While appropriation of surface water is sanctioned by the laws of some of the States, it is more or less difficult, if not impossible, for the legal mind to clearly perceive how such an alleged right can possess either of the essential elements of permanency or absolutism, except and unless the entryman owns the drained area or has some contract right by which he may forever demand unobstructed flow of the surface waters. By surface waters I mean, of course, the waters resulting from rains or melting snows. If he has no such title or contract right, it seems more or less clear and certain, as a legal proposition, that, however such a right, or alleged right, may have the support of state legislation, the claimant under it can not hope to so enforce his claim against the United States, or against their grantees of the lands within the drained area, as to charge those lands with the burden of forever serving as a mere dripping pan for the benefit of his lands. On the contrary, it might seem reasonably well settled that the legal owners of such drained lands may employ them in agricultural uses or other lawful ways without regard or concern for such consequential interference with, or absorption of, the surface waters as will practically destroy the right of the alleged appropriator.

Third. As now ordered and provided by the law of most of the several States and Territories, a water right is not appurtenant to the land upon which it is employed, in the sense that it can not be severed; as a consequence, the same right is made use of for the temporary reclamation of several different tracts of public lands claimed by different entrymen, one of these exercising it only long enough to enable him to make the proof required by law, whereupon he transfers it to some other claimant, who would not otherwise be able to secure the use of water, owing to the prior appropriation and often overappropriation of all of the available water. It is a manifest consequence of this condition that there are, in many localities where this practice obtains, large areas of land appropriated under the desert-land law, for the permanent reclamation of which there is no possible source of water supply. It is a common experience to find that there are large quantities of land with whose title the Government has parted under the desert-land law and as to only a very small portion of which has the real and essential purpose of the law been secured. I may properly say that I have traveled through localities in which more or less extensive areas of lands had been disposed of under the desert-land law, and a most critical inspection failed to reveal the slightest evidence that these lands had ever received any treatment different from that to which the yet unappropriated public lands in the same localities had been subjected. Yet I had no reason to doubt, and, in fact, inquiry led to the conviction, that the letter of the law had been complied with, with perhaps some slight evasion and some slight coloring of proof. The situation I observed was simply due to the fact that the entrymen of these lands had not, at the time of original entry, entertained any purpose to permanently maintain the condition of reclamation which they might produce; acquisition of legal title had been followed by concentration of ownership and subsequent abandonment of all irrigation instrumentalities. Lapse of time and the trampling of cattle, to the pasturage of which the lands had become devoted, completely effaced all evidences of ditches and all other means or results of irrigation.

There are other evils of which I might give some illustration if my title to your further patience were greater, but those which I have tried to delineate seem to me to be the most serious, as considered apart from those which are the result of pure fraud and unscrupulous and purposeful violation of the law.

COAL FIELDS OF THE UNITED STATES.

By Marius R. Campbell and Edward W. Parker,
United States Geological Survey.

According to the estimates prepared by the U. S. Geological Survey, the area underlain by workable coal beds in the United States is 496,776 square miles. Of this total area, 480 square miles contain the entire anthracite coal fields of Pennsylvania. The bituminous coal fields are estimated to be contained in an area of 250,051 square miles. The grade of coal between bituminous and lignite, which is designated by the Geological Survey as "subbituminous," is estimated to be contained within areas aggregating 97,636 square miles, while the areas containing lignite aggregate 148,609 square miles. The coal fields are divided, for the sake of convenience in classification, into six main provinces, as follows:

1. The eastern province, containing the anthracite coal fields of Pennsylvania and the bituminous coal fields of the Appalachian region, i. e., those of western Pennsylvania, Ohio, Virginia, West Virginia, Kentucky, Tennessee, Georgia, Alabama, and small outlying areas in North Carolina.
2. The interior province, containing the bituminous coal-producing regions of Michigan, Illinois, Indiana, western Kentucky, Iowa, Kansas, Missouri, Oklahoma, Arkansas, and Texas.
3. The Gulf province, containing the lignite areas of Alabama, Mississippi, Louisiana, Arkansas, and Texas.
4. The northern Great Plains province, containing the lignite subbituminous areas of North and South Dakota, eastern Montana, and northeastern Wyoming.
5. The Rocky Mountain province, containing the bituminous and subbituminous areas of western Montana and western Wyoming, Colorado, Utah, and New Mexico.
6. The Pacific coast province, containing the areas of Washington, Oregon, and California.

During the last few years the Survey geologists have worked in all of these coal areas and have also been making careful estimates of the quantity of coal contained in the beds when mining first began. In making these estimates care has been taken to ascertain how much of the supply is easily available and how much is either not available under present mining and market conditions or is available with extreme difficulty. According to these estimates the quantity of coal contained within the known area of the United States when mining first began was 3,076,204,000,000 tons. Of this quantity a little less

coast	1,830	11,100,000,000	10,900,000,000	22,000,000,000
Total	496,776	1,922,979,000,000	1,153,225,000,000	3,076,204,000,000

The distribution of this original supply of coal, according to grades d accessibility, is shown in the following table:

Tonnage (short tons), by grades of coal and accessibility.

[Original coal supply.]

Kind of coal.	Area in square miles.	Amount easily accessible.	Amount easily accessible and available.	Amount accessible with difficulty.
hracite and bituminous	250,531	1,176,727,000,000	1,176,727,000,000	505,730,000,000
bituminous	97,636	356,707,000,000	216,252,000,000	293,450,000,000
ite	148,609	389,545,000,000		354,045,000,000
Total	496,776	1,922,979,000,000	1,392,979,000,000	1,153,225,000,000

The first mining of coal in a commercial way, in the United States, as in what is known as the Richmond basin, a small area in the stern part of Virginia. Small quantities of coal had been mined re in the latter part of the eighteenth century and it was also in e latter part of the eighteenth and the beginning of the nineteenth nturies that efforts were being made to introduce anthracite coal for el purposes. The first actual records of the production of Virginia al were in 1822, in which year it was reported that 54,000 tons were ined. In 1820 (two years before) 365 long tons of anthracite coal, r 1 ton for each day of the year, had been shipped to distant mar-ets. From these small beginnings of less than a century ago the production of coal has increased until in 1907 the total output of anthracite and bituminous coal approximated 500,000,000 tons. In 1837 the total production of the United States reached, for the first time, a total exceeding 1,000,000 tons, the output being reported from 4 States only—Pennsylvania, Virginia, Kentucky, and Illinois—although Maryland also was producing a small quantity of coal at that time. In 1840 the production amounted to a little over 2,000,000 tons, the output being reported from 13 States. Ten years later, in 1850, the production amounted to 7,000,000 tons; in 1860 it was over 14,000,000 tons; in 1870 over 33,000,000 tons; in 1880 over 70,000,000 tons; in 1890 it approximated 160,000,000 tons; in 1900 it was nearly 270,000,000 tons; and in 1907 it was 480,000,000 tons. The aggregate production to the close of 1907 has amounted to 6,865,097,567 short tons.

Up to the close of 1845 the total production of coal in the United States was 27,700,000 short tons, and since that time the drain on the supply has practically doubled with each decade. The total production to 1845 and decennially since that time has been as follows:

	Short tons.
Up to 1845	27, 677, 214
1846–1855	83, 417, 827
1856–1865	173, 795, 014
1866–1875	419, 425, 104
1876–1885	847, 760, 319
1886–1895	1, 586, 098, 641
1896–1905	2, 832, 402, 746
1906–1907	894, 520, 702
Total	6, 865, 097, 567

It is estimated that for every ton of coal mined and sold, half a ton is lost or wasted, so that the total production of 6,865,097,567 short tons to the close of 1907 represents an exhaustion of 10,200,000,000 tons, or 0.3 per cent of the total original supply, or 0.7 per cent of the coal which is easily accessible and available under the present conditions. The total supply of easily accessible and now available coal left in the ground at the close of 1907 was 1,382,780,000,000 short tons.

Accompanying this statement two charts are presented, one showing the production of coal annually from 1846 to 1907, the other illustrating the average annual production by progressive ten-year periods for the same length of time, the latter chart having been prepared in order to eliminate minor variations due to abnormal conditions. The average annual increase in coal production figured from the average of progressive decades shown on the second diagram is 7.36 per cent, and for the last five progressive decades—1894–1903 to 1898–1907—the rate of increase has been above that average.

DURATION OF SUPPLY.

The total reserve of easily accessible and now available coal is estimated at 1,382,780,000,000 tons. The assumption that a constant output has been reached would be utterly unwarranted. On the other hand, the adoption of the flat rate of annual increase of 7.36 per cent would involve the improbable assumption that the marvelous record of the past and present will be maintained in the future and the production would continue to approximately double every decade. Using the waste allowance, on the basis of this constant rate of increase in production, the 1,382,780,000,000 tons available at the close of 1907 would be exhausted in one hundred and seven years, or by 2015 A. D. Against the use of the flat rate of increase it may well be contended that just as the rate of increase in population tends to diminish, so this rapid increase in per capita consumption of coal can not persist, and a constant annual production will be reached. However, the figures set fifty years ago by statisticians for the probable constant annual production of coal in England have already been exceeded by over 160 per cent.

Mr. Henry Gannett has made an estimate based upon a decreasing rate of increase calculated from twenty-year averages of production. The use of ten-year averages is regarded as unsatisfactory for the reason that one of the decades may consist mainly of a period of prosperity, while the preceding and succeeding decades contain periods of business depression. The twenty-year period, however, is sufficiently long to include a period of prosperity with one of business depression. Taking the four twenty-year periods since 1828, three rates of increase are obtained which show a rapid decrease. The hyperbolic curve computed from these successive rates of increase will indicate the constantly diminishing rate of increase for the successive twenty-year periods. The result obtained by this method is that the easily accessible and available coal will be exhausted about the year 2027, and all coal by the middle of that century. It is recognized that the data upon which this curve has been constructed are few and the curve correspondingly weak. However, in the above estimate all of the data have been given which it is possible to use, and this estimate is believed to represent the best use that can be made of the data at hand.

100 yrs

Inasmuch as America leads the world not only in present production of coal, but also apparently possesses the greatest reserve and certainly is mining coal at much lower cost than any other country, the obvious tendency will be for European countries to look more and more to the United States for their coal supply. Therefore, while our present coal production and consumption are practically equivalent, the export of coal, unless prohibited by federal legislation, must eventually become a factor and increase the coal production in the United States beyond the demands of home consumption. On the other hand, powerful influences will come to bear upon coal production, which favor lengthening the life of the supply. Thus it is to be hoped that with more improved methods in the utilization of coal the increased efficiency per unit may act as a factor in reducing coal consumption, and improved mining methods should likewise decrease the waste percentage. The increased utilization of water power should also tend to decrease coal consumption. Again, as soon as the end appears in sight prices will rise and production diminish, and that progressively. This interference with the law of decreasing increase produced by growing scarcity will, of course, prolong the life of our coal reserves, but at the same time will greatly hamper our industries that depend on this fuel.

With so many indeterminate factors whose importance is realized but can not be measured, prophecy must possess a questionable value.

WASTE IN COAL MINING.

The principal loss or waste attending coal-mining operations is that represented by the quantity of coal necessarily left in the ground as pillars to support the roof. In some cases it is also necessary to leave a foot or more of coal as a part of the roof, because of the unstable character of the material overlying the coal, which itself does not make a good roof. It has also been frequently the case that, where portions of the coal bed have been of inferior quality, only the high-grade coal has been mined and the poorer material left. The coal left as pillars, or as portions of the roof, may be considered a necessary loss, but that which is left because of its inferior quality can not be considered unavoidable waste in any sense, and is frequently of higher grade than coals mined and used in other portions of the country.

Enormous quantities of coal have been lost beyond recovery from the mining of beds lying below, the caving of which, upon the withdrawal of the pillars, has so broken up the overlying strata as to render it impossible to recover the coals contained therein. This has been particularly the case in some of the coal beds of western Pennsylvania, but much improvement has been observed in this regard within later years. Notwithstanding the improvement in this respect it is probable that a large amount of coal will be wasted in the Western States, where a great number of coal beds are closely associated, and also where the intercalated strata are weak, forming poor roofs to the mines.

There are no exact figures as to the actual loss or waste sustained through coal left in the mines in conducting the mining operations, but it has been estimated that it amounts to 50 per cent of the quantity produced and marketed. In some cases, through careful mining and where the conditions are ideal for working, practically all of the contents of the coal beds are recovered. In other cases, particularly when the beds are of enormous thickness, the recovery has not exceeded 30 per cent of the contents. During the earlier days of mining in the anthracite regions of Pennsylvania it was estimated that only 40 per cent of the coal was marketed. This was partly due to uneconomical methods of mining, and partly to the large amount of culm, for which there was at that time no market and which was piled on the ground in unsightly mountains. At the time of the Anthracite Coal Waste Commission, which made its report in 1893, 40 per cent was still considered a maximum recovery. So far as underground workings are concerned, there has been no revolution in the methods employed since that time, but there has been a considerable improvement in the application of those methods, which has resulted in the recovery at the present time of a materially larger proportion of the coal in the ground than was the rule at that date. The earlier methods of mining consisted in leaving comparatively narrow pillars, and in the mining of large rooms the the result was that the pillars were not strong enough to stand the pressure and were crushed beyond recovery. It is now customary to use larger pillars between the rooms, which makes it possible to better control the roof during " robbing " operations and to eventually recover a larger proportion of the contents of the bed.

Material improvements have also been made in the methods of the preparation of coal, so that a much greater proportion of the product hoisted is now being sent to market in merchantable condition. Part of this is due to better and more systematic methods of handling, and part to the saving of small sizes which formerly went to the culm banks. The higher prices of coal and the development of methods for using these small sizes have also made it possible, through washing processes, to rework the small coal formerly thrown on the culm banks, and these are now furnishing several millions of tons of marketable coal annually.

Under present conditions, except in cases where the surface must be maintained, it is estimated that in the Wyoming region of the Pennsylvania anthracite field the recovery for market is from 60 to 64 per cent. In the Lehigh, Mahanoy, and Schuylkill regions the recovery for shipment is estimated at 56 per cent.

When the Anthracite Coal Waste Commission[a] made its report in 1893 the shipments of anthracite had amounted to 820,362,995 long tons, and the total production was estimated to have been 902,000,000 long tons. The commission estimated that for every ton produced, 1½ tons were lost, and the total exhaustion was estimated at 2,255,000,000 long tons. The estimated original contents of the field were 19,500,000,000 tons, and the estimated contents remaining at the beginning of 1893 were 17,245,000,000 tons.

The commission in its report (p. 149) says:

> It is to be doubted whether the total coal won when the field shall be abandoned will exceed 40 per cent of the total contents. An estimate on that basis would show the available marketable coal still now in the ground to be as follows:

	Tons.
Wyoming region	1, 859, 000, 000
Lehigh region	477, 500, 000
Schuylkill region	4, 561, 500, 000
In all	6, 898, 000, 000

> The amount of coal won at the modern colliery due to improvements in mining methods, in the appliances for handling the coal, and in the utilization of the small sizes shows a decided advance over the earlier years of mining; a still further advance will undoubtedly be made in these directions, and the mining of the small beds, where a larger per cent can be won, will all tend to increase the total. Future estimates for a long time will in all probability show an advance in the total per cent won.

What the commission predicted in the foregoing paragraph has to some extent already been accomplished, from the fact that coal is now being mined from beds that were not considered a part of the available reserves when the commission made its report. In mining methods, as previously stated, there has also been a marked improvement, and the writers are of the opinion that it is safe to assume that since 1893 the 1 ton of coal lost for every ton mined is nearer the actual results than 1½ tons lost for each ton mined, and at this rate the available supply at the beginning of 1893 would have been 8,622,500,000 tons instead of 6,898,000,000 tons. The total production from 1893 to the close of 1907 has amounted to 833,187,445 long tons, which deducted from the estimated available supply of 8,622,500,000 tons would leave as the remaining available supply 7,789,312,555 long tons, it being understood that this is only one-half of the coal left in the ground untouched. What may be done in the future in the way of recovery of coal which is now considered an absolutely necessary waste and lost for all time is, of course, a matter of conjecture.

---

[a] The members of the commission were Eckley B. Coxe, of Drifton; Heber S. Thompson, of Pottsville; and William Griffith, of Scranton, Pa.

In the mining of bituminous coal it is estimated that for every ton of coal produced for market one-half of a ton is lost or wasted. The part of this which is represented by the coal left in the mines for pillars, etc., may be materially reduced, but in many cases the recovery of a larger percentage of the coal in the ground can be obtained only by an increased cost of mining; and this in the face of the overdeveloped properties, keen competition, and low selling prices is incapable of accomplishment at the present day unless there be concerted legislative action by the governments of the several States.

There is another and a serious loss or waste in bituminous coal mining which is, like the culm in the anthracite fields, represented by the slack or fine coal necessarily or unnecessarily produced in mining operations. This is particularly the case when the coal is of the "dry" or noncaking variety which can not be used for coke making or which, because it does not fuse in the fire box, fails to make a satisfactory steam fuel. Many thousands of tons of this "slack" coal are thrown on the ground each year, and much of it is burned in order to prevent it from "cumbering the ground" or adding extra weight above the mine workings. A large part of this waste could be prevented by briquetting, but the process of briquetting adds about $1 per ton to the cost of the fuel, which renders competition with cheap fuel in the shape of raw coal impossible. Two of the causes which lead to the production of unnecessarily large quantities of slack are the excessive use of powder and the practice of "shooting from the solid." These reduce the percentage of large-sized or marketable coal and naturally increase the cost of that portion of the product.

Legislation prohibiting shooting from the solid, which would provide penalties for excessive use of powder, would have as one result a larger percentage of lump coal; and thus in a measure enable operators to assume the additional expense involved in the briquetting of such slack coal as is unavoidably produced.

This legislation is the province of the state governments, and it is not too much to hope that before long laws may be enacted against the accumulation of slack heaps or their useless destruction by burning, and this waste prohibited, as that of natural gas has been in some cases.

The question of the waste in the combustion or utilization of coal does not come within the scope of this paper, but as the manufacture of coke is, in reality, a preparation of the fuel for use, attention may properly be called to the enormous waste resulting from beehive oven practice (the method commonly employed in the United States).

In what is known as the beehive oven (so called because of its similarity in shape to the conventional beehive) the coal is partially consumed, or, more properly speaking, the volitile combustible contents are consumed and all of the valuable constituents of the coal, except the fixed carbon, which is left behind as coke, are wasted. These wasted constituents consist of gas, tar, and ammonia. In what are known as by-product recovery ovens, however, the process is one of distillation and the by-products of tar and ammonia and all of the gas, except that used for heating the ovens, are recovered and used.

The United States is far behind Germany and other foreign countries in adopting the economies resulting from the coking of coal in by-product ovens. In Germany at the present time little or no coke is made except in retort ovens. The first ovens of this type in the United States were built in 1893 at Syracuse, N. Y. Up to the close of 1907 the total number of this type of ovens completed was 3,892, while the number of beehive ovens in operation in that year was 94,746. The production from the retort ovens was 5,607,899 short tons of coke and that from beehive ovens 35,171,665 tons.

When the economies which may be effected by the use of the retort ovens have been so clearly demonstrated, not only by the plants which have been constructed in the United States, but more emphatically through the much more extensive development of by-product coke manufacture in Europe, the condition in the United States, as shown by the statistics for the last four years, is somewhat difficult to understand. As previously stated, the production of coke in the by-product ovens of the United States in 1907 amounted to 5,607,899 short tons. It was valued at $21,665,157. The total value of by-products obtained in the manufacture of this coke was $7,548,071, this value and the quantity being distributed as follows:

Value of by-products obtained in manufacture of coke in retort ovens in 1907.

	Quantity.	Value.
Gas .... thousand cubic feet..	20,516,731	$3,130,839
Tar .... gallons..	53,905,795	1,242,530
Ammonia, sulphate or reduced to equivalent in sulphate .... pounds..	125,372,360	3,174,702
Total	....	7,548,071

The gas included in the foregoing statement is the "surplus" not consumed in the coking process and is either sold or used at manufacturing establishments operated in connection with the coke-oven plant. In a few instances where the surplus gas is consumed by the producing companies the quantity is not measured, nor was any value placed upon it in the reports made to the United States Geological Survey. In such cases careful estimates have been made, based upon the average surplus gas obtained from similar coals used at ovens of the same type. The value, similarly estimated, has been placed at from 10 to 15 cents per thousand cubic feet.

The coal consumed in retort ovens in 1907 amounted to 7,460,587 short tons. The quantity of coal used in beehive ovens was 54,485,522 short tons, from all of which the possible by-products are apparently wasted. Assuming that the coal consumed in beehive ovens was of the same average quality as that charged into the retort ovens and that the prices would be not less than 80 per cent of those ruling in 1907, the value of recoverable products which were thus apparently wasted last year amounted to $44,000,000, a sum equal to nearly 80 per cent of the total value of all the coal used in beehive ovens during the year. At the prices which prevailed in 1907 the value of the by-products wasted in beehive coke ovens was a little over $55,000,000.

The value of the by-products from the retort ovens in 1907 was a little more than one-third the value of the coke produced in them.

It should be remembered, however, that beehive ovens are located in the coal-mining regions and that the cost of the coal charged into them represents only a little more than that represented by the expense of mining the coal, whereas in locating by-product recovery plants provision must be made for utilizing or marketing the by-products. It is for this reason that in much the larger number of cases the recovery plants are established near the larger cities and at considerable distances from the mining regions, and the expense of transportation is added to the mining cost of the coal. Hence it is that the value of the coal charged into by-product ovens in 1907 was $15,874,430, or over $2 per ton, while that of the coal used in beehive ovens was $56,956,008, or $1.05 per ton. It must also be remembered that the original cost of installation for a by-product plant is from four to five times that of a beehive plant of equal capacity. These disadvantages are in turn partly offset by the higher percentage yield of coke in the retort ovens and a lower delivery charge on the coke produced. In the case of beehive coke, railroad transportation expense is borne by the coke, while in retort-oven practice all, or nearly all, of the freight charge is borne by the coal..

The total value of the 5,607,899 tons of by-product coke produced in 1907 was $21,665,157, an average of $3.86 per ton. The value of the 35,171,665 tons of beehive coke made in 1907 was $89,873,969, or $2.56 per ton. If we consider that the difference in the value of the by-product coke and beehive coke was due only to the difference in freight charges, then the total value of the entire product of beehive coke made in 1907 would, if made in retort ovens close to the market, have been $135,750,000. On adding to this the value of the by-products that should have been recovered, amounting to $44,000,000 at 80 per cent of the market price in 1907, the total value of the coke and by-products would have amounted to nearly $180,000,000 instead of the value of $89,873,969 for the beehive coke alone. The value of the coal charged into these ovens, however, would have been $108,879,870 instead of $56,956,008. Carrying the hypothesis further, the difference between the value of the coke and by-products if the coal had been coked in retort ovens and the value of the coke alone from the beehive ovens was, say, $90,000,000. From this should be deducted the difference between what the value of the coal would have been at retort ovens and what it was at beehive ovens, i. e., $52,000,000. The remainder ($38,000,000), less the difference in operating expenses, wear and tear, interest on capital, etc., may be considered as approximately the actual net loss in value as the result of beehive coke production compared with by-product coke practice in 1907.

One of the reasons that has been given for the apparent lack of progress in retort-oven building in the last four years is the lack of profitable markets for the by-products of coal tar, and this has contributed to the backwardness of the United States in the development of the chemical industries depending upon coal tar as a raw material, and yet this country is importing coal-tar products to the value of several million dollars annually. It is also well known that the development of the coal-briquetting industry has been retarded because of the lack of assurance of a satisfactory supply of suitable coal-tar pitch for binding material, and there is also an increasing demand for creosoting oils for the preservation of timber.

COAL SUPPLY, PRODUCTION AND EXHAUSTION, BY STATES.

Alabama.—As far as known the earliest record of the existence of coal in Alabama was made in 1834. The first statement of production is contained in the United States Census Report for 1840, in which year the production is given at 946 tons. In 1907 the production was 14,250,454 tons, and the total production from 1840 to 1907 amounted to 164,734,310 short tons, which represented an exhaustion, including the waste in mining, of 247,000,000 tons. The total coal-bearing area of the State is estimated at 14,430 square miles, and the original coal supply is estimated to have been 68,903,000,000 short tons. The exhaustion to the close of 1907 represents a little over 0.3 of 1 per cent, and the production in 1907 was a little over 0.02 of 1 per cent of the estimated original supply.

Arizona.—A small area of 30 square miles in Arizona is estimated to contain 60,000,000 tons of coal, from which there had been no production at the close of 1907.

Arkansas.—As in Alabama, the first production of coal reported in Arkansas was in the census year 1840, when 220 short tons were reported as having been mined in that State. The industry in Arkansas did not develop rapidly during the early years, as the census of 1860 shows a production of only 200 tons, and that of 1880 a total of 14,778 tons. During the last twenty years, however, there has been a marked increase in the production of coal in Arkansas, and the maximum output was reached in 1907, with a total of 2,670,438 short tons. The total production to the close of 1907 amounted to 23,756,401 short tons, equivalent to an exhaustion of approximately 36,000,000 tons. The estimated original supply of coal in Arkansas was 1,887,000,000 short tons, of which the exhaustion to date represents practically 2 per cent. The production in 1907 was equivalent to 0.15 of 1 per cent of the estimated original supply. The total area in Arkansas which contains workable coal or which may contain workable coal or lignite is estimated to be 7,584 square miles.

California.—The coal fields of California consist of scattered areas, of which, with few exceptions, comparatively little is known. The total workable area is estimated to be 500 square miles, and the original contents of the field 1,000,000,000 short tons. Mining in California had its beginning, according to the records of the state mining bureau, in 1861. The maximum production was reached in 1880, since which time the production has been irregular and has shown a declining tendency, this being due in the last few years to the increased production of oil in the State and its use for fuel purposes. The total coal production to the close of 1907 was 5,030,945 short tons, equivalent to an exhaustion of approximately 7,000,000 tons, or 0.7 per cent of the original supply.

Colorado.—Colorado is one of the Western States which is rich in coal resources. The estimated total area of the coal fields is 17,130 square miles, and the original contents of these fields are estimated to have been 371,770,000,000 short tons. Coal production began in Colorado in 1864, but it was not until 1882 that the output reached as much as 1,000,000 short tons. Since that date there has been a steady increase in production, until in 1907 it amounted to 10,790,236 short tons. The aggregate production to the close of 1907 was 112,668,336 short tons, of which the equivalent exhaustion has been 169,000,000 short tons, which represents a little over 0.05 of 1 per cent of the original supply. The production in 1907 was approximately 0.004 of 1 per cent of the original contents of the fields.

Georgia.—The coal fields of Georgia are limited to a small area in the northwestern part of the State, estimated to cover 167 square miles and to have contained, when mining began, 933,000,000 short tons. The census report for 1860 contains the first authentic statement of production in Georgia, and the output in that year is placed at 1,900 short tons. The production of the State in 1907 was 362,401 tons, and the total production to the close of the year was 8,123,696 short tons, representing an exhaustion of 12,000,000 tons. This would still leave in the ground a total of 921,000,000 tons, of which 650,000,000 tons would probably be considered as the available supply, and this, at the rate of production in 1907, would last approximately 1,800 years.

Idaho.—The areas in Idaho known to contain workable coal are placed at 200 square miles, while there are 1,200 square miles which are not known, but which may also contain workable coal. The estimated original contents of the coal fields of Idaho are placed at 600,000,000 tons, from which to the close of 1907 less than 25,000 tons had been mined.

Illinois.—Illinois is the second State in coal-producing importance. The area in Illinois known to contain coal is larger than that of any other State east of the Mississippi River, and if we consider only the known coal areas the coal fields of Illinois cover a wider area than those of any other coal-producing State. The coal-producing area of Illinois is estimated at 35,600 square miles, and the original contents of the fields are placed at 240,000,000,000 short tons. The earliest mention of coal in the United States is contained in the journal of Father Hennepin, a French missionary, who, as early as 1679, reported a "cole mine" on the Illinois River, near the present city of Ottawa. The earliest record of actual mining is that coal was produced in Jackson County in 1810. In 1833 the production is reported to have been 6,000 short tons. In 1907 it was 51,317,146 short tons. The total production to the close of 1907 amounted to 645,868,309 tons, representing an exhaustion of 968,000,000 short tons, from which it appears that the exhaustion to the close of 1907 has been 0.4 of 1 per cent of the total estimated supply. The quantity of coal remaining in the ground at the close of 1907 was 4,664 times the production of that year, or about 2,500 times the exhaustion represented by that production.

Indiana.—The coal fields of Indiana lie entirely in the southwestern portion of the State. They are confined within an estimated area of 6,500 square miles, and contained, when mining first began, 44,169,000,000 tons of coal. Coal mining in Indiana began sometime between 1830 and 1840, and the census of the latter year reported a production of 9,682 tons. In 1907 the production amounted to 13,985,713 short tons, and the total production to the close of that year amounted to 159,440,390 short tons. The exhaustion to the close of 1907 had been 239,000,000 short tons, or 0.54 of 1 per cent of the original supply. Upon these estimates the quantity of coal remaining in the ground in Indiana at the close of 1907 was about 3,000 times the production of that year, and 2,000 times the exhaustion represented by that production.

Iowa.—The coal fields of Iowa are estimated to contain workable coal aggregating 12,560 square miles. To this may be added 5,640 square miles of possible workable coal areas. The original contents of the fields are estimated to have been 29,160,000,000 short tons. From this there has been produced from 1840, when mining first began, to the close of 1907, a total of 141,608,792 short tons, representing an exhaustion of 212,000,000 short tons. The quantity of coal still available at the close of 1907 was 28,948,000,000 short tons. At the rate of production in 1907, in estimating half a ton lost for every ton mined, this supply would last 2,550 years.

Kansas.—The areas in Kansas known to contain workable coal are placed at 3,100 square miles, although in addition to this there are 15,780 square miles which may contain workable coal. The estimated supply, when mining first began, is placed at 7,022,000,000 short tons. From this there has been produced from 1869 (the year of earliest production) to the close of 1907 a total of 91,176,204 short tons. This represents an exhaustion, including loss in mining, of about 136,000,000 short tons, from which it would appear that about 1.9 per cent of the original supply has been exhausted. The production in 1907 was 7,322,449 short tons, equivalent to an exhaustion of 10,000,000 short tons, which would indicate, at the rate of production in 1907, that the known coal supply of Kansas would last approximately 700 years.

Kentucky.—Kentucky is the only one of the coal-producing States which has within its borders areas belonging to two of the great coal fields. The eastern counties of the State are underlain by the coal beds of the great Appalachian system, while the southern limits of the central or eastern interior field are found in the more northern counties of the western part of the State. The eastern areas contain 10,270 square miles, the contents of which, when mining began, are estimated at 67,787,000,000 short tons. The western areas contain 6,400 square miles, the original contents of which are placed at 36,240,000,000 short tons. The total estimated original supply of the State was therefore 104,027,000,000 short tons. Mining began early in the second quarter of the nineteenth century, and it is estimated that from 1829 to 1835 the production ranged from 2,000 to 6,000 tons a year. The production in 1907 was 10,753,124 short tons, and the total production to the close of the year was 122,404,574 short tons, which represents an exhaustion of 184,000,000 short tons, or 0.18 of 1 per cent of the original supply. The quantity of coal left in the ground at the close of 1907 would then be 103,844,000,000 tons, of which approximately 67,000,000,000 short tons would be considered available, or, in other words, the supply at the close of 1907 was 6,700 times the production in that year.

Maryland.—The coal fields of Maryland are confined to a limited area in Allegany and Garrett counties in the western part of the State. This area has an extent of 455 square miles and the original supply is estimated to have been 8,044,000,000 short tons. Mining began early in the nineteenth century, and shipments were made down the Potomac River in 1830. The first shipments by railroad were made in 1842, in which year 1,708 tons were shipped over the newly built Baltimore and Ohio Railroad. In 1907 the production amounted to 5,532,628 short tons, and the total production to the close of that year aggregated 147,606,548 short tons, equivalent to an exhaustion, including waste, of 221,000,000 tons, or not quite 3 per cent of the original supply. The supply still remaining at the close of 1907 was 7,823,000,000 short tons, 1,422 times the production and 948 times the exhaustion represented by the production of that year.

Michigan.—The coal fields of Michigan are the only ones within the drainage basin of the Great Lakes. They occupy an area of approximately 11,000 square miles and are estimated to have contained when mining first began a total of 12,000,000,000 short tons of coal. Although coal mining has been carried on in Michigan for about seventy years, it is only a little more than a decade since it became of any importance as an industry, the production exceeding a million tons a year for the first time in 1901. The total production to the close of 1907 was 13,842,943 short tons, which, including waste, represents an exhaustion of 21,000,000 short tons, or 0.175 of 1 per cent of the total original supply. The production of Michigan in 1907 was 2,035,858 short tons. The supply remaining at the close of that year was, according to the best estimates, 11,979,000,000 short tons, of which 7,986,000,000 tons would be considered as available. This is equivalent to 3,900 times the production of 1907.

Missouri.—The original coal supply of Missouri is estimated to have been 40,000,000,000 short tons, included within an area of 23,000 square miles. The production of the State to the close of 1907 had amounted to 97,618,106 short tons, representing an exhaustion of approximately 146,000,000 tons, or 0.36 of 1 per cent of the original supply. The production in 1907 was 3,997,936 short tons, which is equivalent to an exhaustion of approximately 6,000,000 tons. The supply remaining at the close of 1907 is about 6,500 times the exhaustion created by the production in that year.

Montana.—Montana's scattered coal fields, known to contain workable coals, aggregate 34,067 square miles, while the areas which may contain workable coal, but which are not well known, amount to 17,575 square miles. The original contents of these coal fields are estimated to have been 303,060,000,000 short tons, from which there have been mined to the close of 1907 approximately 24,740,000 tons, representing an exhaustion of 37,000,000 tons, or 0.012 of 1 per cent of the original supply. The production in 1907 of a little over 2,000,000 tons is equivalent to an exhaustion of about 3,000,000 tons, and the coal left in the ground was 100,000 times that exhausted.

New Mexico.—The coal fields of New Mexico aggregate a total area of 18,335 square miles, and the original supply is estimated to have been 163,780,000,000 short tons, from which there had been produced to the close of 1907 a total of 22,325,432 short tons, representing an exhaustion of 33,000,000 tons, or 0.02 of 1 per cent of the original supply. The production in 1907 (2,628,959 short tons) is equal to nearly 12 per cent of the entire production of the coal to the close of that year, while the coal left in the ground is nearly 65,000 times the production in 1907, and over 40,000 times the exhaustion represented by that production.

North Carolina.—Two small areas of Triassic age contain all the coal known to exist in North Carolina. The total area is about 60 square miles, and the original contents of the field are estimated at 200,000,000 short tons. These areas have never been worked to any large extent, and the total production to the close of 1907 was less than half a million tons.

North Dakota.—Although the coal fields of North Dakota are of wide extent, the coal itself is all of lignitic character and of little commercial value at the present time. The total areas supposed to contain workable lignite are placed at 35,500 square miles and the original contents have been estimated at 500,000,000,000 short tons. The production, particularly considering the large supply, has been very small, the total exhaustion to the close of 1907 having amounted to only 4,000,000 tons.

Ohio.—Compared with the supply of coal originally contained within the coal fields of Ohio, the rate of exhaustion has been greater than that of any other State in the Appalachian system, with the exception of Maryland. The estimated original supply contained within an area of 12,660 square miles was 86,028,000,000 short tons. The first record we have of the production in the State is in the year 1838, when 119,952 short tons of coal were mined. Ohio's output was at that time exceeded only by the production of Pennsylvania anthracite and bituminous coal from the Richmond basin. From 1845 to 1875 Ohio ranked second among the coal-producing States. In 1876 it was surpassed by Illinois, and since 1896, when it was surpassed by West Virginia, it has ranked fourth among the coal-producing States. In 1907 Ohio contributed 32,142,419 short tons of coal to the total product of that year. The total output of Ohio mines from 1838 to the close of 1907, a period of seventy years, has amounted to 492,769,358 short tons, representing an exhaustion of 739,000,000 tons, or something less than 0.9 of 1 per cent of the estimated original supply. The production of 1907, which was a little less than 7 per cent of the production to the close of that year, was equivalent to an exhaustion of about 48,000,000 tons. Deducting from the original supply the exhaustion at the close of 1907, there would still be available on January 1, 1908, 85,980,000,000 tons, or nearly 2,000 times the production in 1907.

Oklahoma.—All of the coal in Oklahoma is contained in that portion of the State which was formerly known as the Creek, Cherokee, and Choctaw nations of Indian Territory. The total area underlain by workable coal is estimated to be about 10,000 square miles, and the original contents are estimated to have been 79,278,000,000 tons. Mining did not begin in Indian Territory until comparatively late, the first production reported having been in 1880, when 120,947 short tons were produced. The industry has progressed rapidly, however, and the production in 1907 amounted to 3,642,658 short tons. The total production to the close of 1907 was 39,845,015 short tons, representing an exhaustion of approximately 60,000,000 tons. The quantity of coal left in the ground in Oklahoma at the close of 1907 was 13,000 times the exhaustion represented by the production in that year.

Oregon.—As far as known the earliest record of coal production in Oregon was in 1880, when the output amounted to 43,205 short tons. In 1907 Oregon's production was 70,981 short tons, and the aggregate production from 1880 to the close of 1907 was 1,790,392 tons, which represents an exhaustion of 2,700,000 tons. The total area in the State containing workable coals is estimated at 230 square miles and the original supply at 1,000,000,000 short tons.

Pennsylvania.—The supplies of anthracite coal in Pennsylvania are discussed in another portion of this paper. The bituminous areas in the western portion of the State are estimated to have an extent of 14,200 square miles and to have contained, when mining first began, 112,574,000,000 short tons. The development of the Pennsylvania bituminous coal fields did not begin until about twenty years after anthracite mining was established as an industry, the first production having been reported in the census year 1840, when 464,826 short tons were mined. Up to 1897 the production of anthracite coal in Pennsylvania exceeded that of bituminous, but in 1898 the bituminous production took the lead and has continued to lead since that date. In 1907 the production of bituminous coal exceeded that of anthracite by nearly 80 per cent, and as indicative of the extent to which the bituminous coal-mining industry of Pennsylvania has grown it may be stated that the production in 1907 was nearly three times that of 1897, only ten years before. The total production of bituminous coal in Pennsylvania to the close of 1907 was 1,846,069,253 short tons, which was equivalent to an exhaustion of 2,760,000,000 tons, or 2.5 per cent of the original supply. The exhaustion represented by the production in 1907 was 225,000,000 tons. The supply remaining at the close of 1907 was 109,804,000,000 tons, or 492 times the exhaustion represented by the production of that year.

South Dakota.—The northwest corner of South Dakota contains the southern extension of the North Dakota lignite beds, and it is estimated that about 6,000 square miles of this territory may contain workable lignites. The contents are estimated at 10,000,000,000 short tons, and these are practically untouched.

Tennessee.—The coal fields of Tennessee are contained in a narrow strip in the eastern counties of the State, where the Appalachian province crosses the State in a northeast-southwest direction. Mining began sometime between 1830 and 1840, and the census for the latter year reported a production of 558 tons. Coal mining did not, however, develop into an important industry in Tennessee until after the close of the civil war, and it was not until 1883 that the production reached as much as 1,000,000 tons annually. Since that time it has increased with notable regularity, until in 1907 the production amounted to 6,810,243 short tons. The total area of bituminous coal in the State is estimated at 4,400 square miles, and the total original supply at 25,665,000,000 tons. The total production to the close of 1907 amounted to 84,304,601 short tons, representing an exhaustion of approximately 126,000,000 tons, or about 0.5 of 1 per cent of the original supply. The exhaustion represented by the production in 1907 was approximately 10,200,000 tons, and the supply left in the ground at the close of the year was equal to 2,500 times this exhaustion.

Texas.—The known bituminous coal fields of Texas are estimated to contain 8,200 square miles, and the exploited lignite fields 2,000 square miles. In addition to this there are 5,300 square miles which may contain workable bituminous coal and 53,000 square miles which may contain workable lignite. The estimated contents of the bituminous coal fields when mining first began in Texas were 8,000,000,000 short tons, and of the lignite fields 23,000,000,000 short tons. The exploitation of both the lignite and the bituminous areas is of comparatively recent date, no production having been reported from Texas prior to 1884, and it was not until 1901 that the output reached as much as 1,000,000 tons. The production to the close of 1907 was 14,444,948 short tons, representing an exhaustion of 22,000,000 tons, or 0.07 of 1 per cent of the original supply.

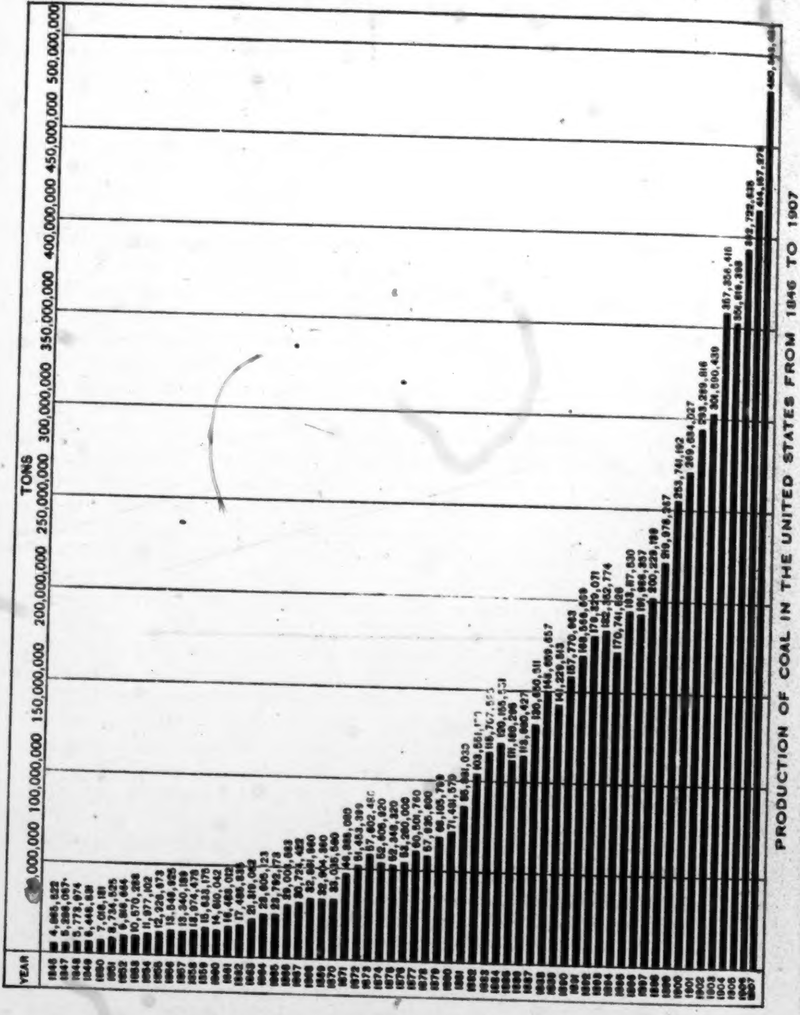
Utah.—Utah's coal fields are contained in scattered areas aggregating 15,130 square miles. The quality of the coals ranges from subbituminous to anthracite. The estimated original supply was 196,458,000,000 short tons, from which the exhaustion, including waste, at the close of 1907, was 28,000,000 short tons, indicating that there were still remaining in the ground 196,430,000,000 tons, or a little more than 100,000 times the production of 1907.

Virginia.—The Richmond basin in Virginia, where coal mining in the United States was first carried on, contains 150 square miles. Another small area in Montgomery County contains 200 square miles of coal-productive territory, but the principal regions are in the southwestern corner of the State, which is crossed by the Appalachian system. The portion of the Appalachian coal field in Virginia is estimated to be 1,550 square miles. The original supply has been placed at 22,500,000,000 short tons. From this there had been produced at the close of 1907 a total of 57,229,152 short tons, representing an exhaustion of 86,000,000 tons. The production in 1907 was 4,710,895 short tons, equivalent to an exhaustion of a little over 7,000,000 tons, so that the coal left in the ground in Virginia at the close of 1907 was 2,000 times the exhaustion represented by the production of that year.

Washington.—Washington's coal supply is contained within a number of areas that are scattered over the State and aggregate approximately 1,100 square miles. The estimated original supply was 20,000,000,000 short tons, and while mining began there as early as 1860, the total production to the close of 1907 was only 43,108,697 short tons, of which nearly 50 per cent was produced within the last seven years. The exhaustion represented by the production to the close of 1907 was 64,000,000 short tons, which is equivalent to about one-third of 1 per cent of the original supply. The quantity of coal still in the ground at the close of 1907 was estimated to be 19,936,000,000 short tons, equivalent to 5,400 times the production of 1907 and 3,600 times the exhaustion made by that output.

West Virginia.—The total area containing workable coal in Virginia is 17,000 square miles, and the original supply when mining first began was 231,039,000,000 tons. West Virginia was not admitted as a State until 1863, in which year the production amounted to 444,648 short tons. The quantity of coal mined prior to that time, in the portion of Virginia which afterwards became West Virginia, was not sufficient to materially affect the total output. For a number of years West Virginia has been third among the coal-producing States, and in 1907 the production amounted to a little over 48,000,000 tons. The aggregate production to the close of 1907 was 434,198,539 short tons, equivalent to an exhaustion of 650,000,000 tons. At the beginning of 1908 there still remained available in the coal fields of West Virginia 230,389,000,000 short tons, nearly 4,800 times the production in 1907, or 3,200 times the exhaustion represented by the 1907 output.

Wyoming.—The estimated original coal supply of Wyoming is larger than that credited to any other coal-producing State, with the exception of North Dakota. In the latter State, however, the entire supply is lignite, while in Wyoming the coals are of subbituminous or of bituminous character. The total area which may contain workable coals has been estimated at 50,793 square miles, and the contents of this field, when mining first began, at 424,085,000,000 short tons. In comparison the aggregate production at the close of 1907, which was 77,818,765 short tons, appears insignificant. The total exhaustion of the beds to the close of 1907 amounted to 116,000,000 short tons, or 0.027 of 1 per cent of the total estimated supply.



PRODUCTION OF COAL IN THE UNITED STATES FROM 1846 TO 1907

ESTIMATES OF FUTURE COAL PRODUCTION.

By Henry Gannett,
United States Geological Survey.

The Geological Survey estimates the amount of coal remaining in the ground to be 3,147,043,000,000 tons, of which about two-thirds is easily obtainable, the other third being of indifferent or poor quality and difficult of mining.

In nearly a century of mining about one-third of 1 per cent of the supply has been taken out of the ground. The production during the year 1907, which was more than 480,000,000 tons, was much larger than in any previous year.

The Geological Survey also estimates that in mining practice about 1 ton of coal is lost for every 2 tons won, either by leaving it in the ground or in breaking and transporting.

In order to reach even an approximate idea of the length of time that this coal supply will last, it is necessary in the first place to estimate the probable annual production in the future. That it will increase beyond the present maximum goes without saying, but at what rates and for how long a period will the increase continue are questions whose solution can only be guessed. Unfortunately we have very few data upon which to build. The rate of yearly increase of production is very irregular, so irregular that no conclusions can be drawn from it. It is impossible to construct from it a smooth curve which might be projected into the future. Even if ten-year averages be taken, and the rate of progress be thus obtained per decade, the result is very unsatisfactory, for the reason that one of the decades may consist mainly of a period of prosperity while the preceding and succeeding decades may contain periods of business depression. It is necessary, therefore, in order to obtain rates of increase which are fairly comparable with one another that we take the rate of production for periods sufficiently long to include a period of prosperity with one of business depression, i. e., twenty years. This has been done with the following results, expressed in terms of millions of tons, each the production of twenty years, with percentages of increase:

Production of coal and rate of increase, by twenty-year periods, 1828 to 1907.

Years.	Production.	Per cent of increase.
	Millions of tons.	
1828-1847	37.3	....
1848-1867	306.0	720
1868-1887	1,451.0	374
1888-1907	5,068.0	249

We have here three rates of increase and they show a very rapid decrease. It would, of course, be folly to assume that the latest rate of increase, 249 per cent, is to continue indefinitely or even at all. There is every indication that the next twenty years will show a great diminution; indeed, at the present rate of increase of production, all the coal would be exhausted before the end of the present century.

The normal curve formed by rates of increase is a hyperbola—that is, if population or production, etc., is not interfered with by extraneous influences, it tends to increase in a constantly diminishing ratio, but never ceases to increase, and the successive rates of increase when plotted to scale form a hyperbolic curve. The equation of this curve, referred to its asymptotes, is $(x-a)\ (y-b)=c$. We have three points on this curve, i. e.:

$$\begin{array}{ll} x=1 & y=720 \\ x=2 & y=374 \\ x=3 & y=249 \end{array}$$

x being periods of time, in this case twenty-year intervals, and y being the corresponding per cents of increase.

Using these values in the above equation, we obtain for the constants:

$$\begin{aligned} a&=13 \\ b&=17 \\ c&=833 \end{aligned}$$

Substituting these values of the constants in the equation, and giving x successively values of 4, 5, 6, etc., the following values for y, the per cents of increase, are obtained, as shown below, with the resulting amount of coal production in each successive twenty-year period:

Estimated production of coal and rate of increase, by twenty-year periods, 1908–2067.

Years.	Per cent of increase.	Production.
1908-1927		*Millions of tons.*
1928-1947	185	21,375
1948-1967	145	52,369
1968-1987	119	114,688
1988-2007	100	229,376
2008-2027	85	424,346
2028-2047	74	738,360
2048-2067	65	1,218,297
	58	1,924,909

The production for the double decade 2048–2067 is estimated at the enormous rate of 274 tons (including waste) for every man, woman, and child in the country, or, excluding waste, 183 tons per capita.

As is seen above, the easily accessible coal may be exhausted about the year 2040, and all coal about the middle of that century; i. e., ten years later.

It must not be supposed, however, that this programme will be carried out. In the first place, the data upon which this curve has been constructed are very few, and the curve is correspondingly weak. They are, however, all that we possess and the foregoing is probably the best way to use them.

In the future, powerful extraneous influences will come to bear on coal production, and all, as far as can be foreseen, except possible exports, are in favor of lengthening the life of the supply.

As soon as the end appears in sight the price will rise and production diminish, and that progressively. This interference with the law of decreasing increase, produced by growing scarcity, will of course prolong the life of our coal reserves, but at the same time will greatly hamper our industries dependent on this fuel.

Again, the development of water power will prove another disturbing factor which will prolong the life of our coal supply. To a great extent, city heating and lighting and power for manufacturing, and transportation will in the near future be furnished by water power. It is estimated that in round numbers 30,000,000 horsepower are going to waste in our streams to-day, most of which can and will be utilized, replacing coal. If all the latent water power in the country were harnessed within the next twenty years, it would probably prolong the life of the coal supply by about eighty years.

Furthermore, the economies to be introduced in mining and handling coal will result in saving a large part of the present waste. If the production and transportation were relieved of all waste within the next twenty years, the coal supply would last twenty years longer.

THE PETROLEUM RESOURCES OF THE UNITED STATES.

By David T. Day,
United States Geological Survey.

EXTENT OF THE PETROLEUM FIELDS.

This report deals with the petroleum fields of the United States as known at present; that is, it is limited to the petroleum pools actually developed, or what is known as "proved territory."

LOCATION.

The areas where petroleum is known to occur at present are shown on the accompanying map of the United States.

Appalachian.—Petroleum is unknown and improbable east of the Allegheny Mountains. Parallel with their western flank the Appalachian belt extends from western New York to Tennessee. It crosses western Pennsylvania, and there petroleum was first found in large quantity. The supply in Pennsylvania is rapidly becoming exhausted. It has declined to one-third of its highest rate of production. This high-production mark was only seventeen years ago. The Appalachian field continues across West Virginia and includes the eastern edge of Ohio. Farther south moderate supplies have long been known, and they are still being developed in Kentucky and Tennessee.

"Petroleum" in this report means crude petroleum, as it comes from the earth; that is, before it has been refined. The word "oil" refers to products obtained from petroleum.

The petroleum of this field (known generally as Pennsylvania petroleum) differs essentially from that of the other fields in the United States. It is notably different from any other petroleum thus far found in the world. It is most easily converted into lamp oil, and yields the greatest percentage of this product. The lamp oil is the finest yet produced—in fact, much better than any other except the products from western Ohio and Indiana, and the petroleum from this latter field costs more to refine.

Farther south, in Kentucky and Tennessee, the product is progressively poorer, but is much better than Russian or any other of the foreign products with which it comes in competition.

Lima-Indiana.—The second great field in historical development covers a considerable portion of northwestern Ohio and eastern Indiana, and small isolated pools of petroleum of the same general character are found elsewhere in Indiana. This petroleum is more

PETROLEUM AND NATURAL GAS FIELDS.

orm than the Pennsylvania varieties. It contains, quite ormly, less gasoline and less lamp oils, and the presence of nic sulphur compounds results in an average of one-half of 1 cent of sulphur, which can be removed only by ingenious and paratively costly refining processes.

linois.—In Illinois, near the eastern edge, a strip of territory e 30 miles long and of irregular width, averaging about 6 miles, ielding a comparatively enormous quantity of petroleum. It is r from sulphur than the Lima-Indiana variety, and occasionally ains sufficient asphalt to ally it to the petroleum from the next to the west, the Mid-Continent field.

id-Continent.—This comprises the pools in Kansas and Okla- a, and must eventually include, for statistical purposes, the ls in northwestern Louisiana and northern Texas. The yield n this field within the last two years has been so large as to greatly urb the industry, on account of the difficulty of providing suffi- t refining and transportation facilities. This petroleum differs n Pennsylvania petroleum in frequently containing small amounts asphalt, and also in containing hydrocarbons less stable in their on toward the chemicals used in refining them. Nevertheless, it proved possible to obtain good yields of perfectly satisfactory ducts covering the entire range from gasoline to paraffin wax. ne of the petroleum of this field contains sufficient water and er foreign materials to complicate the matter of giving it a just uation, and also to add to the difficulty of the refining processes.

n the Mid-Continent field the Glenn pool, located a few miles th of Tulsa, Okla., is a good illustration of the uncertainties of roleum production. A well drilled in 1905 happened to be ated a few feet within the limits of this pool. Had it been located ghtly farther to the east the field would not then have been dis- vered, but the very considerable flow from this well caused more n usual excitement, and nearly all of the wells drilled to the west oved good producers. The wells produced 1,000,000 barrels from 00 acres of ground within the year 1906. Well drilling was rapid, in fact, that the pool reached its maximum production rteen months after the discovery of the first well, and from t time the production declined almost as rapidly as it had in- eased, until the decline was arrested by cleaning out the wells, and terward, also, shooting them with nitroglycerine. The transpor- tion companies could not keep up with such rapid development, d perhaps 1,000,000 barrels of petroleum was wasted on the ound within two years.

Gulf.—For many years the escape of petroleum and natural gas the surface has been noted at many points in Texas and in south- n Louisiana. This led to the drilling, in 1901, of a well at Spindle op, near Beaumont, Tex., from which probably more than 500,000 rrels of petroleum flowed before the well could be checked. The ld was soon extended to Jennings and Welsh, and eventually to nse la Butte, in Louisiana. Other wells were rapidly drilled, re- lting in a large addition to the petroleum product of the United tates. This petroleum contains a large percentage of asphaltum nd relatively small amounts of gasoline and lamp oils, and therefore ffers little temptation to the refiner. It is also handicapped by the resence of sulphur in many forms. For some years it was disposed of principally to the railroads and burned as fuel on locomotives, and thus caused considerable industrial development in Texas, because it was necessary to sell the petroleum at prices as low as 10 cents per barrel in order to find a market for the product. After persistent endeavor it has become possible to refine this petroleum successfully, and some of the products have peculiar value. The lubricating oils find considerable favor and the gasoline has special value as a solvent.

California.—Petroleum, principally asphaltic and similar to the Texas petroleum, except that it is sometimes free from sulphur, is found in many areas in California, between Los Angeles and San Francisco, the principal fields being Los Angeles City, Puente Hills, Kern River, Sunset, McKittrick, Santa Maria, Coalinga, and Fullerton. The lack of an adequate supply of fuel in California has led to very great development of the petroleum industry for this purpose, as shown in the production tables below, and investigations have shown that the quantity of petroleum existing in California is greater than in any other known field in the United States.

Smaller fields.—The great fields described above are those which control the industry. West of the Mid-Continent field and east of the California field are several smaller ones (as thus far developed) in Colorado and Wyoming, with promises of fields in New Mexico, Utah, Idaho, Montana, Oregon, and Washington. In Alaska at least two petroleum pools have been discovered which may possibly be capable of considerable output when the market conditions become favorable.

There are many regions in the United States where there is no geological improbabality of finding petroleum. Such geological improbability exists where the rocks are greatly disturbed and broken up to such a depth as to prevent probable drilling to the undisturbed sedimentary rocks which could furnish good storage for petroleum.

AREAS.

In each petroleum field it has become necessary for the pipe-line companies and for the producers themselves to locate on detailed maps every well as it is drilled, distinguishing the productive from dry wells, in order that the limitations of each field may be promptly determined. From these maps, principally, with the aid of many independent data collected by himself, Dr. F. H. Oliphant has compiled a map of the petroleum fields in the United States, which is appended to this report. From measurements of the areas on this map, together with revisions from the map recently published by Dr. I. C. White, state geologist of West Virginia, and with the aid of Dr. H. Foster Bain, director of the Geological Survey of Illinois; Ralph Arnold, in charge of the petroleum investigations in California for the United States Geological Survey; A. C. Veatch, for Wyoming; Dr. J. A. Bownocker, state geologist of Ohio; and with additional data from Doctor Oliphant, the following table has been compiled, giving in square miles the area of petroleum territory in each State. The figures here given are merely general approximations, which lack very much in uniformity. In some States the area shows simply actual "proved territory." In others, as in Alabama, it indicates the region in which the future production of petroleum is probable. In many others considerable territory is included between individual pools which in all probability will prove to be barren, and while the extensions of "proved territory" will, to a certain extent, offset that which proves eventually to be barren, the table is, at best, a rough approximation. It takes no account whatever of the fact that other fields now altogether unknown will be developed in the future.

State.	Square miles.	State.	Square miles.	State.	Square miles.
Alaska	100	Louisiana	60	Pennsylvania	2,000
Alabama	50	Michigan	80	Tennessee	80
California	850	Missouri	30	Texas	400
Colorado	200	New Mexico	80	Utah	40
Idaho	10	New York	300	West Virginia	570
Illinois	200	Ohio:		Wyoming	750
Indiana	1,000	Eastern	115		
Kansas	200	Western	535	Total	8,450
Kentucky	400	Oklahoma	400		

THICKNESS.

The thickness of the "pay sands" in these fields varies within wide limits. In West Virginia Doctor White considers 5 feet of "pay sand" to be a safe estimate in good producing territory. This is sufficiently liberal for Pennsylvania also. In other fields much thicker "pay sands" are recognized. In Illinois the "pay" streaks in the petroleum sands vary from 2 feet to over 30 feet in thickness, and at Spindle Top, in Texas, an average thickness of over 75 feet has been calculated. In California, particularly in the Kern River field, the "pay sands" reach a thickness of over 100 feet.

POROSITY.

The rocks composing the "pay" streaks in the petroleum-bearing formations of the United States vary from sandstones and dolomites, with the compactness of ordinary building stone, to unconsolidated sands and coarse gravel, and, in exceptional cases, honeycombed limestones, in which actual cavities of considerable size have to be reckoned with. It has been customary to consider 10 per cent as near the average porosity of the "pay sands," with a latitude of variation from practically nothing in damp shales to over 30 per cent in the most porous strata.

The principal effect of these variations in porosity is rather upon the rate at which the petroleum can be obtained from the pool than upon the total amount obtainable.

PROBABLE SUPPLY OF PETROLEUM.

CAPACITY OF SANDS.

Assuming 10 per cent as the average porosity of "pay sands," 1 cubic foot of "pay sand" would yield approximately 1 gallon of petroleum, or 5,000 barrels per acre of "pay sands" with an average thickness of 5 feet.

ESTIMATES OF YIELD.

The thickness most frequently reported for the "pay sands" of various fields is normally much in excess of 5 feet. In Pennsylvania, the reported thickness of petroleum-bearing strata will average more than this, and frequently more than one stratum has been noted in the same well, and yet, as will be shown in the tables of production below, the average yield per acre in Pennsylvania has been less than 800 barrels, and at the present rate of decline it is not probable that more than 800 barrels per acre will be obtained on the average in New York and Pennsylvania. It is fair to assume that 1,000 barrels per acre is a sufficient allowance for New York, Pennsylvania, West Virginia, Kentucky, Tennessee, Ohio, and Indiana. In Illinois, where the yields have been unusually great on account of "pay" streaks approximating 25 feet on the average, Doctor Bain estimates 8,000 barrels per acre as the result of conferences with the producers. This is taking into consideration the fact that in the northern portions of the field the yield is frequently not greater than 2,500 barrels per acre. In the Texas field the supply is better calculated by consideration of the amount already yielded and the rate of decline, from which it is estimated that the Texas fields will surely yield 200,000,000 barrels, and Louisiana 50,000,000 barrels. In Oklahoma the remaining productive capacity is estimated by Mr. W. J. Reed, of the United States Geological Survey, at a minimum of 282,875,000 barrels. In the remaining fields, outside of California, 1,000 barrels per acre is believed to be a sufficient allowance for the known fields.

In California very careful measurements by Mr. Arnold have resulted in an estimate of 8,500,000,000 barrels of petroleum stored in the rocks of that State, of which perhaps 5,000,000,000 barrels may be expected to be produced. Recognizing that the amount of oil obtainable from these known fields is a matter largely of conjecture, it can only be based as above, upon what the fields have already yielded, and upon the thickness and relative porosity of the sands, but estimates of different authorities must vary between wide limits, and this should be borne in mind in considering the following table.

Estimated minimum and maximum total yield of the petroleum fields of the United States.

	Minimum.	Maximum.
Appalachian field	2,000,000,000	5,000,000,000
Lima-Indiana field	1,000,000,000	3,000,000,000
Illinois field	350,000,000	1,000,000,000
Mid-Continent field	400,000,000	1,000,000,000
Gulf field	250,000,000	1,000,000,000
California field	5,000,000,000	8,500,000,000
Minor fields	1,000,000,000	5,000,000,000
Total	10,000,000,000	24,500,000,000

PRODUCTION OF PETROLEUM.

BEGINNING OF THE INDUSTRY.

Production of petroleum in the United States has been considered statistically only since 1859. The production to that date incidental to the salt industry, and the occasional use of petroleum from springs for medicinal purposes, had no bearing on the industry which was to follow, except in one way. Samuel Kier, of Pittsburg, had salt wells at Tarentum, from which he accumulated so much petroleum (more than 50 barrels) that he applied himself to the problem of developing a definite trade for it, and succeeded by means of introducing a lamp with a chimney. He also partly refined this petroleum. A. C. Ferris, also of Pittsburg, applying himself in the same direction, began the distribution of this oil to other cities, and the efforts of these two merchants created and maintained a demand which caused Colonel Drake to drill a well for petroleum at Titusville in 1859. In the course of the half century since the drilling of the Drake well 1,806,608,463 barrels of petroleum, or 240,919,676 tons, have been produced, worth $1,654,877,685. Details of this production are shown in the following table:

Production of crude petroleum in the United States, 1859–1907, by years and by States, in barrels of 42 gallons.

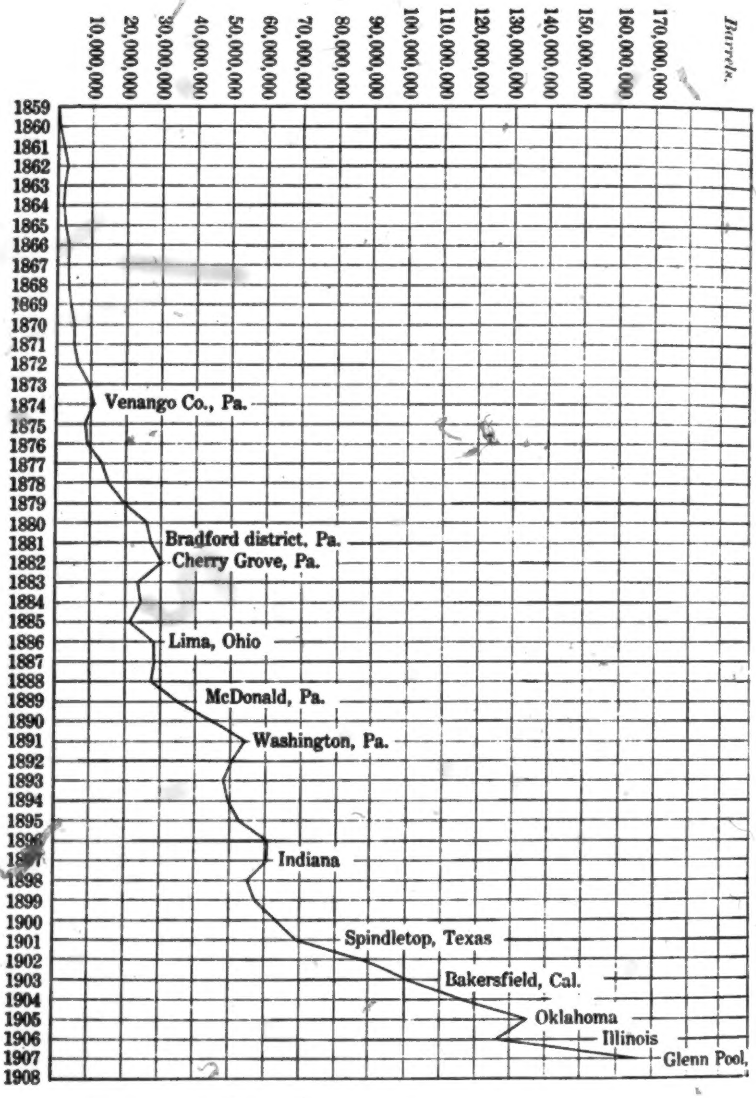
[a] Includes the production of Michigan.

[b] Includes production of Michigan and small production in Oklahoma.

[c] Includes production of Oklahoma.

[d] Included with Kansas.

[e] Estimated.



ANNUAL PRODUCTION OF PETROLEUM 1859 TO 1907.

New petroleum fields have been found and developed so rapidly as to more than offset the decrease of production in the older fields. Therefore, the rate of total production has shown a rapid increase from 500,000 barrels in 1860 to over 166,000,000 barrels in 1907. The rate of production is illustrated by the accompanying curve, on which are noted the sudden impulses resulting from the discovery of new fields. Grouped by the principal fields, the production of petroleum in the United States has been as follows:

Production of petroleum fields in each year from 1859 to 1907.

[Barrels of 42 gallons.]

Year.	Appalachian.	California.	Lima-Indiana.	Colorado-Wyoming.	Mid-Continent.	Gulf.	Illinois.	Total.

[a] Michigan and Missouri not included.

The production recorded above has resulted from the drilling of 287,922 wells, of which 232,982 were productive and 54,940 were dry holes. A distribution of these wells by fields is shown in the following table:

Wells drilled in petroleum fields in each year from 1859 to 1907.

LIFE OF A WELL.

Varying with the compactness of the "pay sand" and with the pressure of the gas accompanying the petroleum, the productive life of wells varies between the extreme limits of a few months on the one hand to more than twenty years on the other. In many regions in Pennsylvania the hard and compact sandstones have resulted in wells of unusually long life, such wells having an initial production of 50 to 500 barrels in the first twenty-four hours and "settling down" to a comparatively steady production of perhaps one-tenth of that amount. This has continued for years with gradual decline, and after even twenty years many of such wells are still being pumped, with a production declining to one-tenth of a barrel per day. The other extreme, of short-lived wells, is represented by the Spindle Top type, where, from very loose sands, wells have spouted many thousands of barrels in the first twenty-four hours, have shown a correspondingly rapid decline, and have become exhausted and been abandoned within six months to four years from the time when first drilled. The experience of petroleum producers in Pennsylvania has shown seven years to be a fair average life of a well.

Adopting this average for the Appalachian, Lima-Indiana, Illinois, and Mid-Continent fields, four years for Texas, six years for California, and seven years for the minor petroleum fields, tables have been computed showing the probable number of active wells which contributed to each year's production. This has been done by adding to the existing wells all the new productive wells drilled in each year and subtracting all wells when they reached the prescribed age limit. From these tables the average daily yield of the wells of each region has been estimated:

Average production per well per day in each field from 1859 to 1907.

[Barrels of 42 gallons.]

Year.	Appalachian.	California.	Lima-Indiana.	Colorado-Wyoming.	Mid-Continent.	Gulf.	Illinois.	Average.

DURATION.

PRODUCTION CURVE.

The rate of petroleum production, graphically portrayed in the curve already referred to, shows that beginning with 1860 as much petroleum has been produced in each nine years as the entire product preceding this nine years. Continuing this rate of increase the next nine years would produce 1,800,000,000 barrels, making the total amount extracted up to 1916 3,600,000,000 barrels. In 1925 the amount extracted would reach 7,200,000,000, and in 1934 14,400,000,000 barrels, and nine years more, 1943, would bring the total to almost the maximum amount estimated as obtainable from the present fields. Concerning the probability of such a rate of increase in production, one must consider the causes for the great increase in past years. The vital factor has been the ease with which any quantity of oil could be sold for cash at any time and for prices ordinarily much above the cost of production. This ready market has not been seriously disturbed even by the greatly increased production of the past few years. The second reason is based upon the liquid character of the product. With the discovery of each new field the territory is divided into many leaseholdings, frequently small in size. In pumping from one lease petroleum is apt to flow in from a rival interest. It is therefore necessary for each lessee to "get his share" before it flows away to drained territory. It is impossible to prevent the consequent rapid depletion of a field without a combination of all the interests, or by limiting by statute the amount that each producer shall extract per acre within a specified time. General industrial conditions have had little effect in regulating the production of petroleum, as has been the case with coal. The purchaser for cash has always been on hand. Even if the price paid has been low, it has been above the cost of production. The surplus has been readily marketed abroad, or burned as a substitute for coal.

Oil's independence of industrial conditions is also shown by the inability of the production to respond to greatly increased trade demand. It requires the development of new territory to greatly increase the production. Otherwise the developed fields rapidly fall into the stage of decline, which is more or less rapid as the oil sands are loose or compact. Without the opening of new territory there is no probability of continuing the indicated rate of increase. The production of the present year could not be maintained beyond a very few years. The duration of the supply will thus be extended, but with a production inadequate to legitimate demands, as the production in the past has been excessive.

Under conditions of an insufficient supply, the relations of price to production must more closely follow supply and demand, the conditions governing which have been pointed out in connection with our better known supply of coal, but there must always remain the exceptional feature of rival producers vieing in the extraction of petroleum from the same reservoir.

RAPIDLY DECLINING FIELDS.

The production tables show that in seventeen years Pennsylvania and New York have decreased to a third of their greatest output.

The decline has become quite regular, and, logically extended, will render the production negligible in ten years. The production per well per day has fallen from a maximum average of 207 barrels to 1.7 barrels, showing that increasing the number of wells is not significantly effective in stimulating the product. In fact, many very old wells are contributing to the product with as little as one-tenth of a barrel per day.

The production in West Virginia has declined to 56 per cnt of the maximum output, and new developments of great magnitude are not looked for. This State is also in the rapidly declining class.

The rate in Kentucky and Tennessee is not easily predicted, but there is no territory which has yet been proved to rank among the great producers. Ohio and Indiana are declining more rapidly at present than Pennsylvania. In Texas the decline is also rapid, and a total of only 200,000,000 barrels is estimated from the present pools. In Kansas the decline has been rapid and the production has now reached a small fraction of the previous yield and a stage where the future decline will be slower.

INCREASING TERRITORY.

Illinois and Oklahoma, in the Mid-Continent field, and California can be expectd to show greater yields. In Illinois the limitations of the new fields have not been reached, and the possibilities of considerable extensions render an increase in the yield probable for several years. The same is true in Oklahoma, particularly in the so-called "shallow pool."

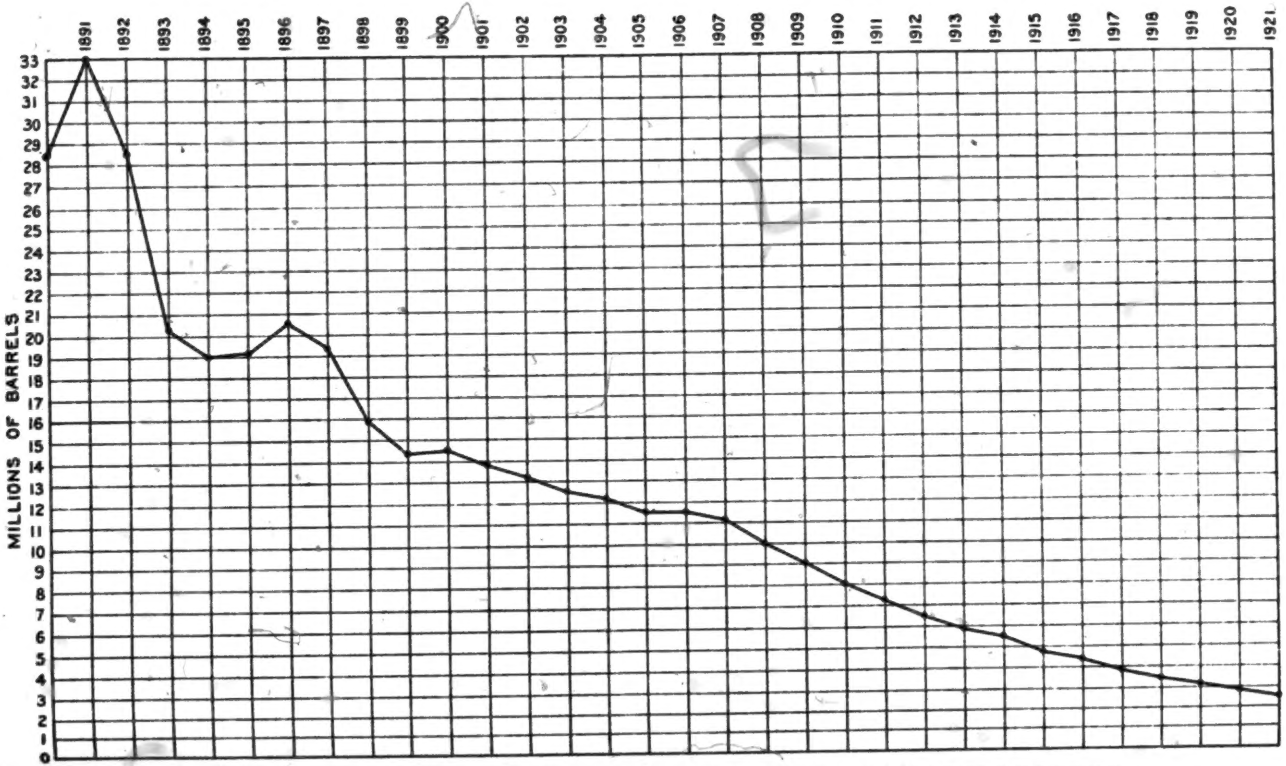
TIME OF EXHAUSTION.

Regarding the limits of time within which the present supply will be exhausted, it is clear that considering the minimum quantity of petroleum in the United States as 15,000,000,000 barrels, and continuing the present rate of increase in production, the supply would be exhausted about 1935. If the present annual production were continued without increase, 90 years would be required to exhaust this estimated minimum quantity. A reasonable view of the situation makes it probable that the present annual rate of production will be increased slightly through the developments of Illinois, Oklahoma, and California, but that within a very few years a marked decline will be noted, and this will continue with increasing value for the oil product and an insufficient quantity for the legitimate demands of the industry after another decade, and that the production, on a reduced scale, will continue for a long time, but in an amount unsatisfactory to industrial necessity, except as supplemented from new fields.

NATURE AND EXTENT OF WASTE IN THE EXTRACTION OF PETROLEUM.

STORAGE.

Waste, as understood in the natural-gas industry, has been markedly absent with petroleum. Very rarely has it proved impossible to furnish storage for some exceptionally prolific gusher. In 1907 lack



DECLINE IN PRODUCTION OF THE NEW YORK AND PENNSYLVANIA OIL FIELDS AND ITS PROBABLE RATE IN THE FUTURE.

of storage in the Mid-Continent field resulted in wasting a large amount of petroleum, estimated at 1 per cent of the total production, for which no storage was available. A similarly exceptional waste resulted in 1901 from the unexpected gushers in the Spindle Top pool in Texas.

LACK OF FORESIGHT ABROAD.

The record of the United States in providing sufficient storage in steel tanks is far better than that of the other petroleum fields of the world. In Russia lack of foresight in opening unusually strong gushers has not only led to repeated enormous waste of petroleum, but to fires which have involved the destruction of large cities. Nowhere else in the world have the emergencies of the petroleum production been met with the keen foresight and prompt treatment characteristic of the United States.

EVAPORATION.

Another form of waste of petroleum products of Europe and of the East, which has been avoided in the United States, is evaporation of gasoline and of similar light products when the petroleum is exposed to the air in open tanks. These light products form the most valuable portion of petroleum. A thin layer of any ordinary light crude petroleum will become heavy and valueless by exposure to the sun for a single day. This has been a source of great loss in the open earthen tanks which have been much used in Russia. In the United States, on the other hand, only under very exceptional circumstances has the earthen tank been used, and then only pending the completion of steel tankage. The rapidity with which steel tanks, often holding as much as 55,000 barrels, have been constructed, to the extent of farms of these tanks, is a remarkable tribute to the engineering skill of the oil-transportation companies. It is due, also, to the conditions of the iron industry, which make it possible to furnish suitable steel promptly for such emergencies. On an average, one tank per day was completed in the Mid-Continent field in 1907.

WASTE IN THE USE OF PETROLEUM.

The principal waste in the petroleum industry is connected with its utilization. In the face of an approaching scarcity, the use of petroleum should be limited to the purposes for which it is essential and for which no other material can be substituted.

ESSENTIAL USES.

Petroleum may be regarded as indispensable for the lighting of isolated houses, and for every small establishment not in connection with a gas or electric supply. The prices at which lamp oils can be sold are lower than the prices of any substitute under isolated conditions. The economic necessity, therefore, of securing the greatest amount of illuminating oil from crude petroleum is evident.

ABSOLUTE NECESSITY OF OIL FOR LUBRICATION.

A still more essential use of petroleum is for lubricating all bearings in every kind of machinery. This is necessary in the development of power by any means. The following table gives some indication of the amount of lubricating oil consumed in various kinds of power production. At least one-half pint of lubricating oil is used for every ton of coal converted into power, and when this power is carried further to its ultimate uses, such as the moving of railroad cars, and when account is taken of the machinery depending on hand power, including sewing machines, clocks, watches, etc., this necessary oil is probably doubled in amount. The conservation, therefore, of a proportionate amount of lubricating oil, consistent with all industrial activity, must become a part of the general plan for civilized progress. It should be noted that from 10 to 15 per cent is as large an amount of lubricating oil as is now obtained from crude petroleum.

Average amount of lubricating oil required for power.

	Gallon of oil per ton of coal.	Gallon of oil per horse-power day.	
Street railway power station	0.168	0.0021	Including crank case, cylinder, and engine oil.

UNNECESSARY USES.

In 1907 there were 18,855,691 barrels of crude petroleum burned as fuel in locomotives, and a large proportion of the California production was used for the development of power, principally by burning it for the generation of steam. Whenever a large increase is made in the production of petroleum with a corresponding decrease in price, the producers are grateful for any outlet for their oil and sell it for such low-grade uses, in which it brings not more than one hundredth part and has brought as low as one thousandth part of the maximum price for high-grade petroleum products. Much of this crude petroleum, had it remained stored in the ground, could later have been converted into far more valuable products. Much petroleum has been used for oiling roads. The skillful application of petroleum residues to poor road surfaces has proved so effective that this use is justifiable, but the use of crude petroleum for such purposes can seldom be considered in any other light than as a waste, especially as coal-tar residues and waste products of the coking and illuminating-gas industry serve this purpose well enough.

EXPORTS.

The greatest waste of petroleum has been in exporting crude petroleum and petroleum products to foreign countries. The necessity for it has been due to the sudden increase of production, due to the discovery and immediate development of the larger fields, and only by this means has it been possible for the producers to continue the practice of furnishing a constant market for petroleum, wherever produced. This immediate purchase of the product has meant a gain of millions of dollars to the producers.

METHODS OF PREVENTING OR LESSENING WASTE IN THE PETROLEUM INDUSTRY.

CHECKING UNNECESSARY PRODUCTION.

At present, more petroleum is being produced than is necessary for the legitimate demands of the industry. Within ten years the present fields will be unable profitably to produce enough for these legitimate requirements. Inasmuch as the lands now owned by private interests are leased by rival concerns, it is impossible to prevent each rival from producing petroleum as rapidly as he desires. The only direction in which production can be checked is with the petroleum contained in public lands. Offering such public land for entry at a nominal price is nothing more than temptation to the private citizen to waste petroleum by overproduction, since lands yielding hundreds of dollars per acre in this product can be obtained for a nominal sum. Every acre of public land believed to contain supplies of petroleum or natural gas should be withdrawn from every form of entry and should be subjected to an equitable system of lease. By this means undoubtedly a large amount of petroleum would be reserved for use when the supply becomes inadequate to industrial demands. It should be noted that since the advance copies of this report appeared in the public press, the petroleum producers of Oklahoma have arranged to reduce production in that State.

BETTER COMBUSTION.

The use of petroleum as a form of power is justified on the Pacific coast, provided attention is given to securing the maximum amount of power per unit of oil. This is not consistent with burning oil under stationary boilers for the production of steam, but prompt study should be given to the development of internal-combustion engines capable of using crude petroleum or, more particularly, less valuable residuum. It should be noted that private enterprise has already done much for the successful solution of this problem.

HOW SUPPLIES OF PETROLEUM MAY BE EXTENDED.

PREVENTION OF WASTE IN EXTRACTION AND IN USE.

Legislation tending to the capping of gas wells in petroleum fields, to preserve the pressure, and to prevent the unnecessary encroachment of water, should be extended to all States where petroleum is produced. After the practical exhaustion of the field by this encroachment of water, the remaining petroleum can frequently be washed into smaller but still profitable pools—a system which is already intelligently used in this country.

DISCOVERY AND DEVELOPMENT OF SUBSTITUTES.

Alcohol from grain, potatoes, and waste products can be used in the place of petroleum as an illuminant and for power in place of gasoline whenever the necessity arises. No practical substitute is known for mineral lubricating oils. Animal and vegetable oils are excluded as entirely too expensive. The production of artificial petroleum from various vegetable and animal waste products has received sufficient study to indicate the possibility of good results if scientific research is encouraged in this direction.

NECESSITY OF SCIENTIFIC RESEARCH.

The most practical recommendation seems to be the encouragement of scientific research in the study of the conditions of occurrence of petroleum in the earth, in order to lessen the expense of discovery of new pools. A second line of scientific research of even greater value should include fundamental studies of the nature of all kinds of petroleum, with a view to converting less valuable varieties into higher grades and to producing greater proportions of the absolutely necessary lubricating oils from crude petroleum. Such scientific study should be initiated at once to be of benefit when the present petroleum supply becomes inadequate.

RECOMMENDATIONS.

Three conclusions are self-evident from this report.

First. It is absolutely necessary for the preservation of an adequate supply of petroleum that all public lands where petroleum is probable should at once be withdrawn from entry.

Second. A general investigation of the conditions of accumulation of petroleum and its geographic distribution should be undertaken in order that the petroleum-bearing public lands may be selected.

Third. Fundamental scientific study of the nature of petroleum, especially with a view to securing the greatest yields of the most valuable constituents and even for transmuting one oil into another, is required for its most intelligent use.

NATURAL-GAS RESOURCES OF THE UNITED STATES.

By David T. Day,
United States Geological Survey.

THE GAS FIELDS.

DISTRIBUTION.

The conditions favorable to the accumulation of gas reservoirs are in general the same as for petroleum. The two usually overlap. More or less gas is always found dissolved in crude petroleum, and the amount of gas obtained at a given pressure from a sand of slight thickness leads to the belief that the gas is dissolved in the petroleum under pressure, in a manner similar to the solution of carbonic acid in water. Reservoirs filled with dry gas are often found—almost always in the neighborhood of petroleum fields—though beds of coal often yield natural gas, even when far from oil wells, as in the anthracite mines of Pennsylvania, where gas is found more than 100 miles distant from any petroleum pool.

AREAS.

The areas shown on the petroleum and gas map, accompanying this report, comprise the regions in which either natural gas or petroleum is the more valuable product. The limits of these areas have been revised since the map was published, and they now show the following measurements in square miles:

State.	Square miles.	State.	Square miles.	State.	Square miles.
Alabama	40	Missouri	70	South Dakota	80
California	310	Montana	40	Texas	130
Colorado	80	New York	550	Utah	40
Illinois	50	Ohio:		Washington	70
Indiana	2,460	Eastern	110	West Virginia	1,000
Kansas	550	Western	165	Wyoming	120
Kentucky	290	Oklahoma	1,000		
Louisiana	110	Oregon	20	Total	10,055
Michigan	40	Pennsylvania	2,730		

PRESSURE.

Estimates of the total yield, in cubic feet, which can be expected from the gas pools are ordinarily obtained by measuring the pressure with a Pitot tube, calculating by a simple formula the cubic feet per day, and observing the rate of decline.

The closed or rock pressures in various fields, in so far as reliable records are available, are given in the following table for various years:

Pressure of natural gas in various fields at various dates.

[In pounds per square inch.]

	Illinois.	Indiana.	Kansas.	Kentucky.	New York.	Ohio.	Oklahoma.	Pennsylvania.	Texas.	West Virginia.
1885	400-450					450		150-575

[e] Bureau County.
[f] Allen County.
[g] Neosho County.
[h] Reduced to almost no pressure.
[i] Beaumont.
[j] Homer.
[k] Southern Indiana.

The paucity of actual data is evident from the table above. It is useful only in showing the generally rapid decline of the high pressures.

PRODUCTION.

The following tables show the value of the natural gas thus far produced. It has been possible only in the last two years to determine the quantity, in addition to the value of gas produced, but this shows that the quantity produced, as well as the price, is increasing.

Approximate value of natural gas produced in the United States, 1882-1907, by States.

PROBABLE DURATION OF THE SUPPLY OF NATURAL GAS.

The duration of high pressures in the known fields is very short. There is no probability of the pressures exceeding 100 pounds per well after ten years. The rate of decline is a peculiar one. At first very rapid, it would be expected that the decline in pressure would follow a simple rate, but it does not. Many wells are still showing a slight but appreciable yield by pumping them after the pressure became negligible. The yield from these low-pressure wells is surprisingly persistent. Evidently the territory drawn upon by them is much larger than was expected. The pumping of natural gas in order to utilize the entire supply is the most hopeful element in the outlook for a continued supply. It is this feature which made possible the use of a larger quantity of natural gas last year than the year before. The outlook is that natural gas will be utilized for as long a period as has already elapsed since the industry began, with the greater part to be furnished by the Mid-Continent field.

NATURE AND EXTENT OF WASTE IN THE EXTRACTION OF NATURAL GAS.

Waste of natural gas will be divided into three classes: First, waste incident to the discovery of a natural-gas field; second, waste in oil production; third, waste in consumption.

WASTE FROM HIGH-PRESSURE WELLS.

It has been a common experience in the discovery of a gas field to encounter pressures so great as to lead to great difficulty in capping, and thus confining the gas until needed. Noted instances of this were the Homewood well near Pittsburg, the Karg and Adams wells in Ohio, the Caney Fork well in Kansas, and, more recently, the wells of the Caddo field in northwestern Louisiana. Individual wells among these have wasted as much as 25,000,000 cubic feet per day, or sufficient gas to supply the entire consumption of three cities the size of Washington, D. C. In the Caddo field at the present time the waste of this character is estimated at 70,000,000 cubic feet per day. In this case wells are drilled through the gas-producing stratum in search of petroleum, which is usually found a few hundred feet below. The natural gas is cased off, but usually, owing to lack of skill on the part of the driller and indifference to the waste of gas, the gas escapes around the casing in increasing volume as the earth is loosened from around the pipe, and finally the force of the gas is sufficient to blow the casing entirely from the well. This has happened in four wells already in the Caddo field. When a well is thus "blown out" little effort has been made to close it. It has been the practice to set fire to the gas for an advertisement to the region.

WASTE OF GAS FROM OIL WELLS.

The production of more or less gas is incident to the drilling of all oil wells, and in most of them, by the time the petroleum-bearing sand is reached, the escape of gas is very great. Taken altogether, the waste of gas by this means is much greater and much more difficult to prevent than the waste from high-pressure gas wells.

In the first days of oil-well drilling in Pennsylvania, natural gas was a nuisance and a menace to the oil producer. This menace became greater with the volume of the gas. It developed a hostility toward natural gas on the part of the oil-well driller, which has increased rather than diminished up to the present time. It is to this hostility that the present waste of natural gas in oil regions is due. When natural gas was encountered in a sand above the expected oil stratum, it always cost considerable money to case it off and pack it in order to continue the drilling, and frequently caused explosions, tearing out the side of the well and occasionally blowing out the casing, causing the ruin of the enterprise. Every oil well now drilled includes in its outfit pipes connected with the casing for carrying the natural gas to a safe distance. Frequently it is burned to get rid of it, sometimes under the boiler to supply power for the well drilling and pumping. This practice has become so general that it is a common custom to pay $5 per twenty-four hours for the power for a well-pumping station. When the natural gas contains appreciable amounts of hydrogen sulphide, with the consequent injury to health, its presence is proportionately less welcome.

It is difficult for the oil-well driller to obtain a prompt and profitable market for the natural gas, whereas with oil it is only necessary to connect the well to a tank, and the cash for the product can be obtained within a few hours. Occasionally, when the pressure due to natural gas is greatly relieved, oil is found. The oil-well driller has accepted this exceptional case as a rule, and is apt to give all possible vent to the gas in the hope of its being followed by the desired petroleum. As to the amount of natural gas which is being wasted daily, no accurate statistics have been attempted, and the judgment of Dr. I. C. White,[a] state geologist of West Virginia, may well be accepted, to the effect that no less than 1,000,000,000 cubic feet of gas are wasted every twenty-four hours. Of this undoubtedly the larger part is wasted in the production of oil. Pumping the oil leaves the wells more or less open, and prevents any careful saving of the gas.

---

[a] Conference on the conservation of natural resources, White House, "Waste of fuel resources," p. 5.

WASTE IN CONSUMPTION.

Directly associated with the waste of natural gas by allowing it to escape freely from oil and gas wells is the form of waste where the gas is used, by delivering it through pipes back into the ground in oil wells below the oil-bearing stratum, so that it will spray the oil to the surface. The mixture of oil and gas then runs into a tank where the oil is saved, but usually the gas is allowed free vent to the outside air. The lack of care in saving the gas after thus using it is a good example of the carelessness with this material prevalent in the oil fields.

Where natural gas is utilized for power, heat, and the lighting of dwellings and has once entered the pipe lines of the distributer, the waste is comparatively small, and little can be said at the present time in regard to any serious loss due to ineffective consumption. Much is used for lighting with incandescent mantles, an efficient use which leaves practically nothing to be desired. A still greater quantity is burned in stoves or in grates, under conditions which are also efficient. For power purposes there is little excuse for burning gas under boilers for the generation of steam, when so much greater economy can readily be produced by consuming it in internal-combustion engines, and the adoption of the gas engine in the place of steam should proceed with far greater rapidity than at present. The following table, prepared by Dr. F. H. Oliphant in 1892,[a] shows that nine-tenths of all the gas used could be saved by substituting internal-combustion engines for the kind of steam engines in use in the oil regions.

Comparison of fuel per indicated horsepower per hour for different types of engines.

Type of engine.	Cubic feet of gas.
Large natural-gas engine, highest type	9
Ordinary natural-gas engine	13
Triple-expansion condensing steam engine	16
Double-expansion condensing steam engine	20
Single-cylinder and cut-off steam engine	40
Ordinary high pressure, without cut-off, steam engine	80
Ordinary oil well pumping steam engine	130

METHODS OF PREVENTING OR LESSENING THE WASTE OF NATURAL GAS.

What has been said above concerning the substitution of gas engines supplied with natural gas, instead of burning natural gas under steam boilers, is a matter of small moment compared with the prevention of escape of natural gas into the air. Our total consumption of natural gas in the United States in 1907 was 404,000,000,000 cubic feet per year, whereas the amount wasted—not burned at all—was estimated at practically the same amount. Thus only half of all the natural gas actually produced goes to any useful purpose. This waste should furnish light for half the urban population of the United States. Remedy for this waste by legislation has been extremely effective in Indiana, Ohio, and Pennsylvania. Only a part of the credit for stopping natural-gas waste is due to legislation, much credit being due to the natural-gas companies themselves for taking the initiative in this reform and carrying it out with most commendable vigor. As a result, the waste of natural gas in these States has practically ceased. Great precautions are now used for the suppression of every flambeau or open gaslight. They are only to be seen at the present time occasionally in connection with the drilling of oil wells. These precautions in late years have not been due so much to legal restrictions as to the efforts of the natural-gas distributers to economize in every direction in the saving of natural gas. The laws of Pennsylvania, West Virginia, Ohio, and Indiana call for the efficient capping of every natural-gas well when not in use. This, however, does not prevent the escape of natural gas where it is an incident of oil production. In this field a more practical plan will depend on the cooperation of the natural-gas and oil-collecting companies, by which the oil producer may receive pay promptly for natural gas to be collected by the natural-gas companies from his oil well. In West Virginia the oil-collecting companies and the natural-gas collecting companies are usually simply branches of the same company, and this plan of collecting gas from the oil wells is already being carried into effect. The ingenuity and watchfulness of the natural-gas companies has effected far greater saving in natural gas than was believed possible five years ago. The result is in evidence from the gain in production in Pennsylvania and West Virginia, where high pressures have practically ceased.

---

[a] Mineral Resources, 1892.

EXTENSION OF NATURAL-GAS SUPPLIES.

PREVENTION OF WASTE IN EXTRACTION AND IN USE.

It is of prime necessity that the laws concerning the capping of natural-gas wells, which have had such good effect in the principal oil and gas producing States, should be extended to the newer fields in the Southern and Southwestern States, and that the most radical measures should be taken to promptly suppress the great waste in these fields at the present time. When effective laws are in operation controlling the escape of gas from high-pressure wells, the problem will be reduced to saving the gas from the oil wells—a problem which can be solved only by affording a prompt and efficient market for the gas, even when produced in small quantity. Meantime, the problem of compressing natural gas in steel cylinders for small-scale transportation is receiving much consideration. Within the next few years success will undoubtedly be attained in returning the natural gas to reservoirs within the earth, which have proved to be sufficiently tight to hold the gas under heavy pressure. Experiments in this direction, costing more than $125,000, are being carried out in Ohio.

INCREASING EFFICIENCY IN USE.

This has already been sufficiently referred to in a previous paragraph.

DISCOVERY AND DEVELOPMENT OF SUBSTITUTES.

Unlike petroleum, natural gas can be replaced efficiently, at least for all practical purposes, by fuel gases produced by methods which are already well understood and are being studied with great care by the technologic branch of the United States Geological Survey. This substitution of fuel gas is well understood. The replacement of the artificial gas for the natural will regularly follow the trade relation of price. It is known that many large culm banks and other amounts of refuse coal are already owned by the natural-gas companies in anticipation of their utilization at the place where they occur, for making and distributing gas to distant points of consumption. This long-distance transportation of natural gas has been developed on so large a scale between West Virginia and Cleveland, Ohio, that the transmission of fuel gas over long distances is now also being studied as a certain feature of future industrial progress.

PEAT RESOURCES OF THE UNITED STATES EXCLUSIVE OF ALASKA.

By Charles A. Davis,
United States Geological Survey.

Peat as a source of fuel and power, as well as the raw material upon which may be based a number of industries, has but recently attracted general attention in this country. It has, however, long been used in northern Europe, where it is estimated that in the neighborhood of 10,000,000 tons prepared in various ways are consumed as fuel annually, and smaller amounts are used as stable litter, for sanitary purposes, and in various trades and arts.

It has been assumed by engineers, economists, economic geologists, and others, because of the abundance and cheapness of good coal and wood in the United States, that peat could not be used profitably in competition with them, at least for a long time to come.

Recent developments in the utilization of low-grade fuels in producer-gas engines, and the very considerable successful use of peat for the generation of fuel, illuminating and producer gas in Sweden, Germany, Russia, and other countries of Europe, have made a marked impression on those scientists and others in America who have followed the march of events in this direction. and these developments have aroused new interest in the possibility of using peat as an auxiliary fuel.

Already preliminary experiments have been made by the technologic branch of the United States Geological Survey with a large gas producer, which confirm the reports of foreign success in this direction, showing that some peats of American origin are little inferior to many grades of bituminous coal now on the market, and superior to some in the quantity of producer gas to be derived from them and in the calorific value of the gas.

Still more recent than this work is the report from Germany that by the investigations of Doctors Frank and Caro it is possible to recover a large part of the combined nitrogen contained in peat, while it is being converted to gas in the gas producer, as ammonium sulphate; and that where the nitrogen is present in amounts slightly above 1 per cent of the dry matter of the peat, the quantity of ammonium sulphate obtained pays the expenses of maintaining the plant, of gasifying the peat, and a profit besides, leaving the gas as an additional profit. As many American peats have more than 2 per cent of combined nitrogen and a considerable number of analyses show above 3 per cent, it is probable that in the near future peat beds will be profitably utilized for the production of power and ammonium salts in the United States.

This is the more likely when it is considered that the region of most abundant occurrence of peat in large deposits lies along the northern border of the country and in the eastern Coastal Plain. There are also smaller areas where it is found, as in the western mountains and in the moister portions of the Pacific slope. The States containing the greatest amount of peat are the eastern Dakotas, Minnesota, Wisconsin, Michigan, northern Iowa, Illinois, Indiana and Ohio, New York, the New England States, New Jersey, the coastal portions of Virginia, North and South Carolina, Georgia, and practically all of Florida. It is also assumed that there are workable peat beds in the swampy parts of the Gulf States and in those portions of the flood plain of the Mississippi remote from the stream.

It will be noted that these regions of frequent occurrence of peat are practically all outside of the coal fields, with the exception of Michigan, where, as is well known, the coal basin has not been found to be productive except in limited marginal areas, very small in comparison with that of the entire basin.

As a sign of the times it may be stated that work is about to begin in Florida on a plant for generating electric power by producer-gas engines using air-dried peat as fuel, the power to be transmitted to Jacksonville. Aside from other phases of the question it should be remembered that peat can be mined and prepared for the gas producer by the simplest and most inexpensive equipment, and with a minimum of danger, since all of the workings are open cuts made by the use of spades, or of ordinary excavating or dredging machinery, so that none of the dangers of underground mining are encountered.

On the other hand, the great drawback in the preparation of peat for fuel or other uses has always been and continues to be the fact that it contains from 85 to 90 per cent or more of water as it comes from the beds, and that the greater part of this water can not be pressed out but must be removed by evaporation. Peat which is air dry contains from 15 to 25 per cent of water, and its theoretical efficiency is lowered thereby in nearly direct proportion to the amount of water present.

In gas producers of recent types, however, it is reported that peat with 40 per cent water has been used with success, and for this purpose the question of excess of water has apparently been solved by plowing or digging up the peat and allowing it to dry out by exposure to the wind and sun on the surface from which it is taken. In Florida, even in midwinter, peat taken from below the water level, ground in a pug mill, and afterward spread over a drying ground in a layer 8 inches thick, dries to the air-dry state in about three weeks, and is ready for use in a gas producer in less time.

The question of artificially drying peat for fuel has received and is now engaging the attention of able engineers and inventors, and, in the opinion of many, the successful solution of this problem is necessary before any considerable increase in the use of peat for ordinary fuel can be expected.

Briefly stated, the matter rests upon the finding of a way to handle peat with about 90 per cent of water rapidly and cheaply enough so that the 250 pounds of salable material, which will result when it has reached the air-dry state, will pay the cost not only of the processes of preparation, but also of management, amortization, and selling, and return a profit on the original investment. Attention should be called to the fact that if peat with 90 per cent water has its moisture content reduced to 40 per cent, it loses more than half of its content of water, and that this amount is readily extracted by very simple and inexpensive processes.

In Europe, peat is prepared for fuel in several ways designed primarily to render it transportable and efficient as a source of energy. As cut peat it is used extensively for domestic purposes in the form of air-dried sods or blocks cut by hand with specially designed spades. A more compact and efficient fuel is made by more or less thoroughly macerating the peat and pressing it into molds, after which it is dried by spreading the blocks on the ground, exposed to sun or wind, or by grinding it in a specially constructed pug mill similar to that used in grinding clay for making bricks. The peat is ground wet as it comes from the beds, and delivered from the mill in the form of wet bricks, which on exposure to the air and sun's heat for some time become dry, firm, tough, and nonabsorbent. This is machine peat, which is rated the most generally successful form of peat fuel for domestic and boiler use on the markets of Europe. As marketed, this product contains from 20 to 25 per cent of moisture and has, theoretically, about 65 per cent of the fuel value of the same weight of good bituminous coal when burned in stoves or under boilers, but practically, because of the lack of waste of the peat, in the form of ash, smoke, clinker, and unconsumed portions, its real value is higher than is indicated by comparison of the possible heat units to be obtained.

As peat briquets the material is more compact, burns more slowly and persistently, and stands transportation and handling well. The peat is dried thoroughly, powdered, and briquetted, either without or with a binder or in mixture with coal or lignite.

An increasing amount of peat is manufactured into charcoal or peat coke, especially in Germany, where it is used somewhat extensively as a substitute for wood charcoal in smelting iron and in other metallurgical processes, including the refining of copper, steel making, etc. Of the processes so far developed for the manufacture of peat coke none have proved profitable on a commercial scale, except such as condense the distillates and recover a series of by-products similar to those obtained by the destructive distillation of wood, viz, fuel gases, methyl alcohol, acetic acid, lime acetate, ammonium salts, tar and its derivatives. This process involves large preliminary investment and the maintenance of costly plants, but where a good market can be found for the by-products this seems to be justified, according to unbiased and trustworthy reports from Europe. In preparation for coking, the peat is treated exactly as if it were to be sold as machine-pressed peat and is stored in open sheds until needed for the coking retorts.

An increasing amount of peat in the form of powder burned with blast burners is used abroad for firing under boilers and in brick and cement burning; where properly prepared and the firing rightly controlled it approaches theoretical efficiency when used in this way.

The production of gas from peat, as has been stated, has passed beyond the experimental stage, and peat gas is used for mettalurgical purposes, boiler firing, making lime and brick, and to some extent in making glass, while a rapidly growing number of producer-gas plants for using peat are being installed for generating electric power for transmission directly from the larger peat deposits to centers of use.

In view of all of these considerations the following estimates of the peat resources of the United States have been prepared with the view of at least directing attention to the very considerable source of wealth to the nation which is now lying entirely undeveloped in the swamps and bogs of the country. It will also be noted in considering the possibilities of the peat deposits that they furnish potential substitutes for wood in various departments of industry, and in some considerable degree in these directions may relieve the drain upon the vanishing forests.

In making the estimates given below it has been the aim of the writer to be conservative in every detail, and it is believed that in no case will they be found too optimistic.

The total swamp area of the United States, exclusive of Alaska, is estimated to be 139,855 square miles.[a] Of this 8 per cent is assumed to have peat beds of good quality, or 11,188 square miles. The peat in this area is assumed to average at least 9 feet in depth and to contain 200 tons of dry fuel per acre for each foot in depth, or a total of 12,888,500,000 tons. Its value, if converted into machine peat bricks at $3 per ton, would be $38,665,700,000. The value if coked and the by-products of distillation saved would be as follows:

Quantity and value of peat coke and by-products from peat deposits of the United States.

	Product in tons.	Value.
Peat coke	3,608,800,000	[a]$26,005,300,000
Illuminating oils	257,800,000	4,474,200,000
Lubricating oils	90,200,000	
Paraffin wax	38,700,000	3,479,900,000
Phenol	167,500,000	66,345,100,000
Asphalt	25,800,000	824,900,000
Wood alcohol	43,800,000	7,844,000,000
Acetic acid	56,700,000	2,268,800,000
Ammonium sulphate	39,900,000	2,777,400,000
Combustible gases	738,400,000	6,501,300,000

[a] Charcoal price. At coke price the value would be $9,024,200,000.

The better grades of peat coke are nearly free from sulphur and phosphorus, and may be used wherever hard-wood charcoal is required. The quantity of wood required to make charcoal equivalent to the amount of the peat coke given in the estimate would be approximately 8,019,800,000 cords. The uncondensable gas given off from the retorts while the peat is being converted to coke has good fuel value, the maximum being about 300 B. t. u. per cubic foot, and has been successfully used for heating the retorts and for other fuel purposes.

If converted into producer gas by the most recently developed processes, so that the combined nitrogen of the peat is converted into ammonia and fixed as ammonium sulphate, there would be possibly available 619,257,511,000,000 cubic feet of producer gas, with a calorific value of 145 B. t. u. per cubic foot. Assuming 1.5 per cent of nitrogen as an average content of the peat, which is low, since many analyses show more than 3 per cent, 100 pounds of ammonium sulphate to the ton of peat treated in the gas producer could be obtained.

---

[a] Sixtieth Congress, first session, S. Doc. 151.

On this assumption there is stored up nitrogen enough in the peat to supply at least 644,400,000 tons of ammonium sulphate, having a value of $36,732,400,000, in addition to the gas produced.

Recent tests reported from Europe show that from 2 to 2.5 pounds of peat will produce an effective horsepower per hour, if reduced to gas in a properly designed gas producer and used in the gas engine. Taking the larger amount, to be conservative, it is evident that there is stored up in the peat beds of the country, as estimated above, energy sufficient to develop 10,310,860,800,000 effective horsepower hours.

In Europe great quantities of the more fibrous types of peat are manufactured into stable litter, for bedding live stock, and peat mull, or powder, for absorbent and sanitary uses. Of this class of material it is estimated that there are at least 2,578,000,000 tons available. This class of material is superior to straw and other substances now generally used for the purpose, and would readily bring $10 per ton, or the whole amount has a prospective value of $25,780,000,000. The only factory (located in Indiana) now making a product of this class in the United States sells its entire output of several hundred tons per annum at about $12 per ton.

A single plant for making paper from peat is in operation in Michigan. Possibly 5 per cent of the total amount of the peat of the country is suitable for this purpose, or 644,400,000 tons. The use of this material would reduce the consumption of wood for the purposes of making coarse papers and pasteboard, by whatever amount it displaced wood pulp in the manufacture of such materials.

In the United States peat is being somewhat extensively manufactured into fertilizer filler, material used in making various grades of artificial fertilizers in which slaughterhouse and other refuse animal matter rich in nitrogen are ingredients or in which hygroscopic mineral compounds are used. Peat in the form of dry powder is especially adapted to this use, since it absorbs water and ammonia readily, is a deodorizer, and to a considerable extent prevents fermentation and decomposition. At the prices now obtained for peat suitable for this purpose in the form of dry powder, and considering one-half of the total amount suitable for the purpose, its value is estimated to be $38,666,000,000, or about the same as the valuation of the whole for ordinary fuel.

Ethyl or "grain" alcohol has been made from the less thoroughly decomposed peats in Denmark and Sweden at a cost estimated at about 47 cents per gallon.

If 10 per cent of the entire body of peat in the country can be used in this way, about 70,900,000 tons of alcohol can be obtained from peat. It must be said in passing that this process is as yet hardly past the experimental phases.

Artificial wood, a fireproof or slow-burning composition of peat and mineral cements, has been made in Germany on a small scale for paving blocks and similar uses, as well as for larger structural purposes, as a substitute for wood or stone in buildings. About 10 per cent of the entire peat deposits of the United States may be suitable for this composition, or 1,288,800,000 tons, the use of which would release an equivalent amount of sawed lumber for other uses or to be held in reserve against future need.

Fibrous peat, properly cleansed of the finer material associated with it, is finding a constantly growing use in Europe as packing material for fragile or perishable articles, and for protecting and insulating water and other pipes subjected to the liability of freezing. The peat best adapted to this use is too light in weight and too loose in texture for fuel manufacture, and may be estimated to occur to the amount of 500,000,000 tons, with a market value of $3,000,000,000, displacing excelsior, hay, straw, paper, and other similar materials which are now used.

Fabrics of various qualities and kinds, mattresses for hospitals, and fiber for surgical and other asceptic dressings and as a substitute for silk in cloth weaving have been made from certain grades of peat, but the market is so well supplied with other products for the same purpose, which are of as good or better quality, that the use of the peat products has never reached any extensive commercial scale and does not seem likely to do so in the near future.

It is clearly apparent, however, that in the peat beds of the United States there lies undeveloped—even entirely untouched—a vast amount of raw material from which may be derived, by intelligent and conservative exploitation, fuel, power, fertilizing material, and the raw materials from which may be made a number of valuable products, all of which will serve to supplement other resources which are now known to be limited in quantity. By utilizing these resources also the wealth of the nation may be possibly increased by the not inconsiderable sums which represent the potential cash value of the peat beds and their products, and an equivalent amount of other material will be rendered free for other purposes.

ABSTRACT OF ESTIMATE OF THE PEAT RESOURCES OF THE UNITED STATES.

Peat, a fuel used in Europe to the amount of 10,000,000 tons per annum, is an almost unknown material in the United States, although possessing properties which make it an excellent domestic fuel and desirable for gas production on a large scale.

As the area of the peat beds in the United States, and the quantity of workable material which they contain, is almost unknown, the estimates submitted are but rough approximations. The following are sources of information used here: (1) Publications and topographic maps of the United States Geological Survey; (2) reports of the state geological surveys of New York, Michigan, Iowa, Indiana, Massachusetts, and New Jersey; (3) cooperative reconnaissance peat surveys undertaken by the United States Geological Survey and the state surveys of Connecticut, Maine, and Wisconsin; (4) personal observation of the writer in various parts of the country.

The total area of swamp land is estimated by the United States Geological Survey[a] to be 139,855 square miles. The writer estimates 8 per cent of this to have peat beds which would average 9 feet deep, or 11,188 square miles, with an average possible production of 200 tons of dry fuel per acre-foot, or a total of 12,888,500,000 tons.

The greater part of this material occurs in that part of the country without productive coal fields, in eastern North and South Dakota,

---

[a] Sixtieth Congress, first session, S. Doc. 151.

Minnesota, Wisconsin, Michigan, New York, and the New England States, in northern Iowa, Illinois, Indiana, Ohio, in the coastal plain region, in eastern New Jersey, Virginia, North and South Carolina, Georgia, and the whole of Florida. The swamp areas of the Gulf States and of the flood plain of the Mississippi River, as well as those of the Pacific States, also contain workable peat beds, but in none of these is there any considerable overlapping of the peaty areas into workable coal fields.

It is estimated that, in the vicinity of the beds, this quantity of peat would have a value of $3 per ton in the form of air-dry blocks, or a total of $38,665,700,000, and that once established on a commercial basis the entire product would find ready sale as fast as produced. If this peat were all used in by-product gas producers, to this value as fuel may be added the value of 644,400,000 tons of ammonium sulphate, which at present prices would be worth $36,732,400,000.

Peat has been successfully used as a source of producer gas, of a form of charcoal or coke, of various by-products from the coke retorts similar to those obtained from wood distillation, of fuel and illuminating gas, of fertilizer filler, and of paper, litter for stables, and packing materials. In these forms the prospective value of the total peat of the country is much larger than as peat fuel.

IRON ORES OF THE UNITED STATES.

By C. W. Hayes,
United States Geological Survey.

INTRODUCTION.

No previous inventory of the iron-ore supplies of the United States in any detail has ever been published, and the present one must be considered only a first approximation which will be materially modified as new quantitative data are made available by future public and private investigations. The estimates of ore supplies given in this paper are not based upon the judgment of any individual, but so far as possible represent the consensus of opinion of those best qualified to form an opinion. Cordial cooperation in making up the estimates has been given by officers of private corporations and the several state geological surveys and by economic geologists and mining engineers generally. Special acknowledgments are due to Messrs. W. N. Merriam, C. K. Leith, D. H. Newland, H. M. Beuhler, W. S. Bayley, T. L. Watson, R. C. Hills, and J. F. Kemp, who have furnished information which could not have been obtained from any other source.

CHEMICAL CLASSIFICATION.

The commercial ores of iron, on the basis of chemical composition, fall into two main classes, i. e., oxides and carbonates. The latter class is relatively unimportant, furnishing in the United States less than one-twentieth of 1 per cent of the annual production. The oxides are further separated, according to the proportion of oxygen and combined water which they contain, into three classes. The chemical and commercial classification is therefore as follows:

1. *Magnetite.*—Magnetic oxide, Fe_3O_4, including titaniferous magnetite. Theoretical iron content, 72.4 per cent. Generally containing some hematite.
2. *Hematite.*—Anhydrous sesquioxide, Fe_2O_3, including specular and red hematite, red fossil ore, oolitic ore, etc. Theoretical iron content, 70 per cent.
3. *Brown ore.*—Hydrous sesquioxide, $Fe_2O_3nH_2O$, including turgite, limonite, goethite, or a mixture of these minerals, known locally as brown hematite, bog ore, etc. Theoretical iron content, 59.8–66.2 per cent.
4. *Carbonate.*—Siderite, iron carbonate, $FeCO_3$, known locally as spathic ore, black band ore, kidney ore, etc. Theoretical iron content, 48.2 per cent.

GEOLOGIC CLASSIFICATION.

In their geologic relations and mode of occurrence the iron ores may be further classified as follows:

1. *Magmatic segregations in basic igneous rocks.*—The titaniferous magnetites of the Adirondack region represent this type. A characteristic of such deposits is the perfect gradation from the ore into the surrounding rock by an increase in the gangue, which consists of the same minerals as the associated igneous rock. The deposits are of great size and present large possibilities of utilization by concentration or with modification of furnace practice which will permit their economical reduction.

2. *Contact deposits, formed in connection with the intrusion of igneous rocks at their contact with the intruded sediments, generally limestones.*—These appear to be due to ascending heated waters and vapors given off by the cooling igneous rock. The ores include both magnetite and hematite. Typical examples are the Cornwall deposits of Pennsylvania and many of the western iron-ore deposits, as those at Hanover, N. Mex., and Iron Springs, Utah.

3. *Concentration deposits.*—These include all forms of the oxide ores in which the iron, originally disseminated through the rocks, has been dissolved, transferred, and redeposited by circulating waters. It includes most of the brown ores of the Appalachian region in which the iron was originally disseminated through a great mass of limestones and shales and has been leached out and concentrated by surface waters during the erosion of these rocks. In some cases the iron was probably deposited as carbonate or sulphide and subsequently changed in place to hydrous oxide. It includes the bog-ore deposits, which have been formed or are now forming in swamps, to which iron is brought in soluble form as organic compounds and precipitated by the breaking up of those compounds through oxidation.

4. *Replacement deposits.*—These are closely related to the concentration deposits, the principal difference being that the ore-bearing solution has derived the iron from an outside source and deposited it in place of some definite portion of an original rock series, generally a limestone. They include all classes of ores, both oxides and carbonates, their composition depending on the conditions of deposition and the subsequent alterations which they have undergone. An example of this type is the so-called Oriskany ore of Virginia. In this case the iron derived from a great mass of overlying shales has been carried in solution, and where structural conditions were favorable deposited in place of a certain easily soluble bed of limestone for a variable distance from its outcrop.

5. *Bedded deposits.*—These include all deposits in which the ore forms tabular or lenticular bodies which lie parallel to the bedding or foliation of the inclosing rocks. Their origin may be diverse, but their common characteristic is great lateral extent compared with thickness. In many bedded deposits, though not in all of them, the ore is sharply differentiated from the surrounding rocks. Magnetite deposits of this type are the Adirondack ores associated with metamorphic sediments and with gneisses of uncertain origin. Of the hematite deposits of this type are the enormous deposits of the Lake Superior district, where certain beds of the iron formation have been enriched both by the removal of silica in solution and by the depo-

sition of additional iron. It also includes the gray specular ores of Alabama, which are associated with Cambrian and pre-Cambrian slates and sandstones, and the important red ores, fossil and oolitic, which form regular sedimentary beds, differing only in composition from associated Silurian sandstones and shales. Of the carbonates it includes the black-band ores, which occur as layers of nodules or continuous beds associated with the "Coal Measures" in Ohio and Pennsylvania.

6. *Gossan deposits.*—Iron sulphides tend to oxidize with loss of sulphur when exposed to surface weathering, and deposits of pyrite and pyrrhotite are therefore generally covered with a deposit of residual brown ore, which extends down to the level of permanent ground water. Examples of this type are the brown ore on the outcrop of the pyrrhotite veins at Ducktown, Tenn., and the iron-ore capping of many metalliferous veins in the West.

Referred to the ultimate source of the material, it may be stated in general that the iron ores are derived from the iron minerals either segregated or disseminated in igneous rocks or the iron minerals deposited by igneous emanations, which have been worked over in varying degrees by the agents of weathering and sedimentary and chemical deposition at the surface of the earth. Iron compounds are among the most stable substances under surface conditions, and hence the net result of the changes at the earth's surface is to concentrate iron minerals mechanically and chemically as compared with associated minerals.

VALUE OF ESTIMATES.

An understanding of the above chemical and geologic classifications of iron ores is essential for an appreciation of the limitations and uncertainties of any estimate of the ore supplies of the country. It will be readily understood that with the great diversity in type of deposits there must be a very wide difference in the degree of accuracy with which the ore can be estimated. The closest approximation can be made in case of bedded deposits such as the Clinton red hematites. These beds vary in thickness and composition from place to place, but the variations are similar to those characterizing other sedimentary beds such as coal, and with a minimum amount of testing on the outcrop and at depth their contents can be calculated with a fair degree of certainty. Certain assumptions, however, must always be made. Thus it is assumed that observed variations in composition and thickness continue with regularity between and beyond points of observations; also that a certain depth will limit workability. This limiting depth will depend upon a variety of conditions which can not be determined in advance of mining, and hence the depth fixed upon in making calculations will be largely a matter of opinion, and must be expected to change with changing commercial conditions. Hence it is doubtful if even the best known and most thoroughly tested deposits of red hematite can be estimated within 10 per cent of their actual yield. At the other extreme are the concentration deposits of brown ore. These are extremely variable both in depth and horizontal extent. Surface indications are thoroughly unreliable, and those most experienced in working such deposits are practically unanimous in the opinion that no deposit can be safely estimated until every ton of ore has been mined. Under such circumstances the estimates given below of ore remaining in this class of deposits can only be regarded as having a degree of accuracy represented by a factor varying between 0.7 and 3.

Intermediate between these extremes are the most important deposits, including those of the Lake Superior and Adirondack districts. The former by reason of their greater regularity and the thoroughness with which they have been tested may be considered as known within 15 or 20 per cent. The latter are much less fully tested, and estimates of their probable yield are based upon assumptions which further development may prove to be erroneous. Estimates of the western ore deposits vary in value because of inherent uncertainties due to the nature of the deposits and to the very unequal information concerning different districts.

AVAILABILITY.

Any estimate of the iron-ore supplies of the United States must separate the ores into two classes on the basis of availability. This separation is difficult, and opinions vary widely as to where the line should be drawn. Evidently the question is one of costs: (*a*) The cost of the ore delivered at the furnace and (*b*) the cost of reduction. Actual production, past and present, being determined by the interaction of various factors, affords the best criteria of availability.

The two factors which enter most directly into the cost of ore at the furnace are accessibility and mining conditions. Many iron-ore deposits are known in regions so remote from fuel supply and from transportation lines that they may be considered unavailable at present or so long as they are compelled to compete with more accessible ores. At the same time they must be taken into account in considering the total reserves, for accessibility is only relative and no deposit, if sufficiently large to warrant the expenditure necessary for constructing roads, can be regarded as permanently inaccessible. Distance from fuel is, of course, a more serious drawback than absence of present means of transportation, while those supplied with water transportation will bear a longer haul than those carried entirely by rail.

Mining conditions may be such as to make the cost of raising the ore prohibitive at present. Such conditions are limiting depths beyond which mining, on account of the amount of water, may become very expensive, or thinness of the beds which necessitates a large amount of dead work. These conditions apply particularly to the Clinton ores and explain the difference between the total amount proved in these deposits and the amount considered at present available. Many deposits of brown ore can be worked cheaply in open pits for a certain distance from the surface, while the cost of stripping or of timbering to hold back the inclosing clay prevents their working to greater depths.

Another kind of limiting conditions arises from the fact that in many cases the ore is mixed with foreign material from which it must be separated. Thus many of the brown ores consist of small concretions scattered through clay, and a large amount of material must be passed through the washer to obtain the ore in suitable condition for the furnace. The ratio of ore to clay in deposits now being worked varies from 1:5 down to 1:20. When conditions permit the lowering of this ratio still further, large quantities of ore will be available in material which can not now be worked at a profit. Similar conditions control the availability of many of the magnetic deposits, except that here the objectionable elements are other minerals that are closely associated with the iron and must be separated by magnetic methods. The concentrated material is a high-grade ore, and the ratio of available to nonavailable in these deposits depends wholly upon cost of the process of concentration which they will bear in competition with other ores.

The second consideration affecting availability is the character of the ore itself. The content of metallic iron in ores used at present varies from 30 to 65 per cent. This wide variation is due in part to the nature of the other elements in the ore and in part to advantageous location. Thus the Clinton ores, containing as low as 30 per cent iron, can be used with advantage, because the lime which they contain makes them practically self-fluxing. At the same time they must be used near the point of production, since the low content of iron will not permit long transportation in competition with richer ores. On the other hand, siliceous ores containing less than 40 per cent iron are not considered at present available unless their location near the fuel is exceptionally favorable, since the cost of transportation per unit of iron is excessive and since a large amount of fuel is required to remove the silica. But there are enormous quantities of siliceous ore carrying from 35 to 40 per cent iron, particularly in the Lake Superior district, and this must be taken into account as a future reserve, though not at present available.

In the case of the titaniferous magnetites the ratio between the available and not available is difficult to determine. While these ores have been used only to a limited extent because of the difficulties attending the fluxing of the titanium, it seems probable that these difficulties will be overcome and a much larger use made of them either by employing a special flux in the furnace or by reducing the percentage of titanium in the charge by concentration or mixing with nontitaniferous ores.

The percentage of other constituents, such as phosphorus, sulphur, copper, chromium, manganese, and alumina, will determine the method and cost of reduction and the quality of the resulting iron. Hence these constituents, some of which are highly deleterious, may determine the question of availability by limiting the conditions under which the ore can be reduced or the product used.

Another factor is the nature of ownership. Where a large corporation controls a variety of ores and is equipped to assemble them and form any desired mixture or grade, ores may be used with advantage which would not be available if held by a smaller company not in a position to control the situation in a large way or compelled to dispose of a single kind of ore in the open market.

Because of the varying importance of these factors, future availability will obviously vary in a corresponding degree and the advantage which one district now possesses may pass to another. As the higher-grade ores of the Lake Superior region become depleted the lower-grade ores will be called upon with consequent increase in cost of transportation and smelting. The low-grade ores of the southeastern district, at present competing with the high-grade Lake Superior ores, will then have a decided advantage because of proximity to fuel supply.

The notable present tendency in the iron industry is the lower average iron content in the ores used. This tendency will undoubtedly continue in the future as the more easily accessible portions of the richer deposits are worked out. As a corollary to this is the observed tendency toward a decentralization of the iron industry, and with a decrease in the iron content of the ore used, involving a corresponding increase in cost of transportation per unit of iron, there will be an increase in the proportion of fuel which goes to the region producing the ore. This will be accompanied by the general adoption of by-product coking. It is an instructive fact that in certain furnaces now operating in the Lake Superior district the profit corresponds approximately to the value of the by-products from the coke ovens.

In making estimates all of these considerations, together with the best forecast that can be made of conditions as they will exist in the next ten years, have been taken into account in determining the ratio between available and nonavailable supplies.

GEOGRAPHIC AND GEOLOGIC DISTRIBUTION.

Iron being one of the most abundant elements, fourth in order of abundance, its natural compounds are found in practically all rocks and soils. To constitute an ore, however, certain of these minerals must be segregated into deposits of sufficient size and purity to permit economical working. Such deposits, considering the entire area of the country, are relatively infrequent. Iron ore is at present produced in only 29 of the 47 States and Territories, and about 79 per cent of the production (1907) was from two States—Minnesota and Michigan. It is evident that the distribution of the deposits is extremely uneven.

For convenience of description of the ores and discussion of the estimates the known ore deposits will be taken up by groups based on distribution and kind. A few deposits are not included in any of these groups, but the total tonnage of ore which they contain is so small as to be negligible in an estimate of the total for the entire country. The groups of deposits to be considered are the following: (1) Lake Superior ores; (2) Adirondack ores; (3) Clinton ores; (4) Appalachian metamorphic ores; (5) Appalachian brown ores; (6) Appalachian carbonate ores; (7) West Tennessee brown ores; (8) East Texas brown ores; (9) Ozark ores; (10) Rocky Mountain metamorphic ores; (11) Igneous contact ores.

(1) LAKE SUPERIOR ORES.

[Based on information furnished chiefly by C. K. Leith.]

GEOLOGIC RELATIONS.

The Lake Superior ores, chiefly hematites with subordinate amounts of magnetite, constitute approximately 80 per cent of the annual iron-ore production of the country. The total production from the region from its opening to the close of 1907 has come from the ancient folded and metamorphosed pre-Cambrian formations in Michigan, Minnesota, and Wisconsin in proportions shown in the following table:

Geologic sources of Lake Superior iron ores.

State.	District.	Geologic horizon.		
		Keewatin.	Middle Huronian.	Upper Huronian.
		Per cent.	*Per cent.*	*Per cent.*
Minnesota (46.555 per cent)	Mesabi			39.45
	Vermilion	7.105		
Michigan (50 per cent)	Gogebic			12.24
	Marquette		21.90	.50
	Menominee, including Crystal Falls, Iron River, etc.			15.36
Wisconsin (3.308 per cent)	Penokee			1.98
	Menominee (Florence)			1.26
	Baraboo			.068

The iron formations are sedimentary deposits, usually interbedded with slate, quartzite, dolomite, and sometimes with basic extrusives. They consisted originally of chert, containing beds of iron carbonate or of dark-green ferrous silicate granules, called greenalite. As a result of surface oxidation of the iron carbonate and greenalite, the great bulk of the formation within the zone of observation now consists of chert minutely interbedded with limonite or hematite, giving a banded rock variously called ferruginous chert, taconite, or jasper. The average proportion of iron in these siliceous rocks is between 25 and 37 per cent. Numerous slate layers form subordinate proportions of the iron formation.

The iron ores constitute concentrations of ore in the exposed parts of the iron formation, accomplished mainly by taking out the associated silica and leaving the iron in larger percentage, but also partly by solution, transportation, and redeposition of the iron when it is still in its soluble ferrous condition. The agents of alteration are surface waters carrying oxygen and carbon dioxide. The accessibility to the iron formation of these agents therefore determines the location, shape, and size of the ore deposits. The most favorable condition of accessibility is given by wide area of exposure of the iron formation, which is in turn a function of the dip. The flat-lying formation in the Mesabi Range exposes a greater surface to concentrating agents than the steeply dipping formation of similar thickness and character in the Gogebic range, with the result that the proportion altered to ore is much greater in the Mesabi district. A comparison of the actual areas of the different iron formations with their total shipments to date, and with their probable reserves, shows a very close relation between area and amount of ore developed. Also determining accessibility of the concentrating agents to the iron formation are numerous structural conditions, such as joints or faults or impervious pitching basements, favorable to rapid circulation of water. Finally, the texture of the iron formation itself, whether dense or porous, may determine the activity of the circulation of the waters.

It is therefore apparent that the size, shape, depth, and structural relations of the Lake Superior ores are in widest variety. In the flat-lying formations of the Mesabi Range the ore bodies have wide lateral extent as compared with depth, extremely irregular outlines partly controlled by jointing, abut irregularly on bottom and sides against unaltered portions of the iron formation, and when the glacial overburden is removed, are accessible to surface operations with steam shovels. In steeply dipping beds they have greater vertical as compared with horizontal dimensions, usually abut not only against unaltered parts of the iron formation, but against well-defined impervious walls consisting of slate, quartzite, dolomite, or bosses or dikes of greenstone, and in such beds underground mining is necessary. The maximum depth to which mining has extended is a little over 2,000 feet; the maximum horizontal extent thus far worked in a single mine is less than a mile, but deposits are known to connect for nearly 10 miles. An adequate summary of the variety of structural features of the several districts can not be made within the limits of this paper.

CHARACTER OF THE ORES.

The hematites and limonites making up the great bulk of the Lake Superior ores range in texture from soft and powdery to hard and crystalline. Both kinds usually have large pore space, due to the removal of silica by leaching. Locally, however, where the ores have been buried deeply in the zone of rock flowage, they have become dense, schistose, specular hematites and magnetites lacking pore space. Where the iron formation has been intruded by large masses of igneous rocks the ores are magnetic. The ores range in grade from above 60 per cent in iron down to 25 per cent in the lean parts of the iron formation. The average shipment for 1906 for the entire region was 59.8 per cent in iron. The difference between the iron ore and the iron formation is simply in the proportion of silica present.

The ores mined in the Lake Superior region to date have generally run above 50 per cent in iron. The lowest grade shipped has been about 40 per cent, in the case of local ores in demand for mixtures and favored by cheap mining and transportation. In mining much material running 40 per cent or even less is taken out and mixed with higher-grade ores to give a medium grade. Such low-grade material therefore does not figure obviously in the production. The percentage of iron in the ore mined from the region has fallen slowly but steadily in recent years, but the major part of the shipment is likely to remain above 50 per cent for some years to some. In the present estimate of available ores about 50 per cent of metallic iron has been taken as the minimum. It is fully appreciated that ores below this grade are even now locally available and will soon be used in larger quantities, but such ores as a whole must be considered still as belonging to the future supply. The ore supply of the Lake Superior district available under present conditions is therefore taken to include all ore above 55 per cent iron, estimated at 2,500,000,000 tons, and 25 per cent of all ore containing between 45 and 55 per cent iron, giving a total of 3,500,000,000 tons exclusive of the Clinton ores.

ESTIMATES OF LOW-GRADE ORES.

Difficulties beset estimates of the tonnage of low-grade ores available for the future. The lower limit of such grade must be chosen somewhat arbitrarily, and when it is chosen there is lack of sufficient analyses of the iron formation as a whole to separate the tonnage above the given grade. The mixing of high-grade and low-grade ores also complicates the situation. Extensive drilling operations have been directed mainly to determine the percentage of ore above 50 per cent and little attention has been given to the grading of ores running below this percentage. The averages of all available analyses from portions of the formation outside of the ore at present available, made by the mining companies of the Lake Superior district, give the following results:

Character of the iron-bearing formations of the Lake Superior district.

DIAMOND-DRILL CORES.

State.	Holes.	Average iron content.	Analyses.	Total footage.
		Per cent.		
Michigan	77	36.52	3,897	22,202

Levels	....	38.40	905	[a]7,500

[a] Approximate.

It seems entirely probable, in view of the fact that 40 per cent ore is even now locally in demand, that the depletion of the higher-grade reserves may in time require the use of 35 per cent ore. If so, the tonnage is enormous. Planimeter measurements of areas of the iron formation, multiplied by the depths quite within the limits of actual mining at the present time, give the following results:

Tonnage of iron formations.

District.	Area.	Depth.	Volume.	Quantity.
Michigan:	*Sq. miles.*	*Feet.*	*Cu miles.*	*Tons.*
Crystal Falls	7.80	1,250	1.950	19,500,000,000
Marquette	28.50	1,250	7.100	71,000,000,000
Menominee	5.60	1,250	1.400	14,000,000,000
Penokee	11.60	1,250	2,900	29,000,000,000
Swanzy	1.00	1,000	.200	2,000,000,000
Minnesota:				
Mesabi	127.00	400	10.000	100,000,000,000
Vermilion	15.60	1,250	3.900	39,000,000,000
Wisconsin:				
Florence	.70	1,250	.175	1,750,000,000
	197.80	....	27.625	276,250,000,000
Ontario, Canada:				
Animikie	10.80	100	.20	2,000,000,000
Michipicoten	6.64	1,250	1.66	16,600,000,000
Other districts on north shore of Lake Superior	30.00	1,250	7.50	75,000,000,000
	47.44	....	9.36	93,600,000,000
Total	245.24	....	36.985	369,850,000,000

It is not proved, however, that this enormous tonnage will average as high in iron as these figures from the mining companies would indicate. Indeed, many parts of the formations are known to run lower than this. It is regarded safer, therefore, to use a smaller figure for the tonnage of ore running 35 per cent and over. Just what fraction of the total tonnage of the iron formations should be taken is a matter of more or less arbitrary choice. It is here put at 72,000,000,000 tons, divided as shown in the following table:

Estimates of Lake Superior ores.

District.	Available.	Not available.
Michigan:	*Long tons.*	*Long tons.*
Marquette district	110,000,000	15,900,000,000
Gogebic district	95,000,000	3,900,000,000
Menominee, Crystal Falls, and other districts	80,000,000	7,360,000,000
Minnesota:

Wisconsin	40,000,000	4,525,000,000
Total	3,500,000,000	72,000,000,000

(2) ADIRONDACK ORES.

[Based on reports of the New York State Survey.]

The area of crystalline rocks forming the Adirondack district occupies the greater part of the State of New York north of the Mohawk Valley. The district contains a variety of iron ores differing in their character and geologic surroundings. Those found in sufficient abundance to be commercially important are nontitaniferous magnetites, titaniferous magnetites, and red hematites. Some deposits of limonite also occur as bog ores, but they are not generally of sufficient size to be considered an available source of ore at the present time.

The rocks of the Adirondack district, with the exception of small patches of Paleozoic sediments, are entirely pre-Cambrian, and are either wholly crystalline or highly metamorphosed. They are provisionally classed in three groups: (1) Sedimentary rocks, marble, schist, and gneiss; (2) gneisses of undetermined origin, but probably in part, at least, sedimentary; and (3) igneous plutonic rocks, anorthosite, gabbro, syenite, and granite. The first group occupies a relatively small part of the area, but with its various members are associated all of the hematite deposits and many of the nontitaniferous magnetites.

NONTITANIFEROUS MAGNETITES.

These are the most widespread of the Adirondack deposits, but the more important ones occur in two groups on the eastern border of the district in the Lake Champlain basin and in the western part of the district in St. Lawrence County. In the first group are the well-known Hammondville, Mineville, and Lyon Mountain deposits, and in the second the Benson, Jayville, Fine, and Clinton deposits.

The ores show great variation in their mineral and chemical composition, ranging from lean varieties, which consist of magnetite intermixed with the constituents of the wall rock, to those made up of practically pure magnetite. The richest, obtained principally from the Mineville group, average from 60 to 65 per cent iron, and considerable quantities have been obtained which approached the theoretical iron content of magnetite (72.4 per cent). The deposits carrying less than 50 per cent iron are generally considered too refractory for direct smelting and their utilization depends upon concentration. Large bodies of such ore occur in the Lyon Mountain, Arnold Hill, and St. Lawrence County deposits. The lowest grade of ore now worked carries about 35 per cent iron ore before concentration.

Both Bessemer and non-Bessemer ores occur, in some cases in adjoining deposits, though generally the ores from all deposits of a group show a fair degree of uniformity in respect to phosphorus content. The leaner ores are apt to be lowest in phosphorus, and concentrates produced at Lyon Mountain contain less than 0.01 per cent of that element with 65 per cent iron. The ores also carry a variable proportion of sulphur due to the admixture of pyrite and more rarely pyrrhotite.

The deposits occur in a variety of forms such as are common to the magnetites found in gneisses and schists elsewhere. In general they have a lenticular bedded form and are parallel to the foliation of the inclosing rocks. They partake of the same structural folds and faults as these rocks, and must therefore have been deposited before the regional compression occurred to which these structural features are due. While there has been much diversity of opinion regarding the origin of these ores, the view generally held at present is that they were introduced by processes connected with the intrusion of the igneous rocks.

The Adirondack magnetites were mined as early as the latter part of the eighteenth century and supplied many bloomeries and forges and, later, small charcoal furnaces. These have now all disappeared, and the ores are mostly shipped to the iron-making centers for smelting. There are, however, two coke furnaces in the region that are supplied by local mines. The total production up to the present time has been somewhat over 36,000,000 tons. Both open-cut and underground mining methods are employed, but chiefly the latter because of the high inclination of the ore bodies. A depth of 1,500 feet has been reached in the workings at Lyon Mountain, and about 2,000 feet at Barton Hill. Practically all of the ore is concentrated by the magnetic process, which yields concentrates containing from 60 to 65 per cent iron and at the same time effects a partial elimination of the phosphorus and sulphur. In fact, the treatment of the richer ores is designed primarily to reduce the phosphorus, and the concentration is a subordinate object.

While a few of these deposits have been drilled with sufficient thoroughness to permit a fairly definite estimate of their contents, this is not generally the case, and in most cases even the extent of the outcrop is not accurately known. Lines of magnetic attraction indicate the presence of ore bodies concerning which little else is known, and finally large areas in the Adirondack Mountains, heavily forested and drift covered, have not been examined in sufficient detail to determine whether or not they contain iron-ore deposits.

For these reasons it is impossible accurately to determine the ore reserves. It is estimated that the known deposits of high-grade ore will yield 35,000,000 tons, and that the leaner deposits, carrying over 35 per cent iron, will yield 75,000,000 tons of concentrates. The estimate of ore which is not now available because of great depth, or low grade, but which may be used eventually, is even more uncertain, but may be placed conservatively at 25,000,000 tons.

TITANIFEROUS MAGNETITES.

Under this class are included the ores which carry titanium as an essential ingredient. In general it amounts to at least 8 per cent of titanic acid (TiO_2), while the average is perhaps 15 per cent. These deposits occur within the margins of the gabbro-anorthosite area, chiefly in Essex and Franklin counties. In their relations to the inclosing rocks these deposits are sharply differentiated from the nontitaniferous magnetites which occur in the sedimentary and eruptive gneisses and schists. The titaniferous ores are believed to be the product of magmatic segregation, and hence intimately connected in origin with associated igneous rocks. The form of the ore bodies has not been accurately determined except in the case of a few of the smaller ones. The large bodies have nowhere been uncovered or sufficiently explored to afford an idea of their precise outlines. The richest ores contain little else than magnetite and ilmenite, and yield fully 60 per cent iron. From such pure aggregates there may be traced a continuous series of gradations by the entering of gangue minerals in increasingly greater proportion to the limiting wall rocks which hold only subordinate amounts of magnetite and ilmenite. The two minerals are often distinct in their crystallization, and show no tendency toward mutual intergrowth.

The use of ores containing high percentages of titanium is generally regarded as impracticable under present furnace practice because of the infusibility of the slags. They have, however, been smelted on a small scale in the Adirondacks, as well as in England and Sweden, and experiments have shown the feasibility of securing a fusible slag by properly proportioning the fluxes. A more promising solution of the problem is found in a reduction of the amount of titanium entering the furnace, both by concentration and by employing these ores as mixtures with nontitaniferous ores. Since the ilmenite is only feebly magnetic, it has been found practicable, at least on an experimental scale, to reduce the titanic oxide from 15 to 8 or 9 per cent by moderately fine crushing and magnetic concentration.

These deposits have been explored only far enough to prove that they contain a very large amount of ore which simply awaits the development of methods for overcoming the metallurgical difficulties due to the presence of the titanium. Assuming that these difficulties will be overcome, it is estimated that the known deposits in the Lake Sanford district alone contain at least 90,000,000 tons sufficiently accessible and high in grade to be now available, and that they may contain in addition 100,000,000 tons, which are not now but will be eventually available as an ore supply.

RED HEMATITES.

Hematite deposits of workable dimensions occur on the northwestern side of the Adirondacks in Jefferson and St. Lawrence counties. They are associated with the folded pre-Cambrian sedimentary (Grenville) series of schists, limestones, and gneisses, which attain greater areal development in that section than elsewhere in the Adirondack region. The ores are mainly soft, red hematites, with subordinate specular, and occupy zones of replacement along the contact of crystalline limestone and schist, and at times in the schist itself, with often a capping of Potsdam sandstone. A peculiar feature is the presence of a greenish mineral—locally called serpentine, but of chloritic nature—which seems to be an alteration product formed by reaction of the iron-bearing solutions upon the feldspathic schists and the occasional granitic intrusions of the walls. The source of the iron may be traced with some certainty to bands of pyrite and magnetite, which abound in the schists and which are subject to rapid weathering and to solution by ground waters. The principal mines have been opened along a narrow belt extending northeast from Antwerp nearly to the village of Gouverneur, but there are a number of outlying deposits that have been worked in former days for the supply of local furnaces. Mining was begun about 1835. Altogether the district has furnished probably 2,500,000 tons of non-Bessemer ore ranging from 45 to 60 per cent iron. The largest mines are the Dickson and Old Sterling near Antwerp and the Caledonia and Spragueville. Of recent years the output has been shipped to New Jersey and Pennsylvania for reduction.

Aside from the actual mine workings the district is practically unexplored, and it is impossible to draw any accurate conclusions as to the quantity of ore that may exist. Judging from the ore bodies developed in the mines recently operative, it seems safe, however, to place the resources at present available at 2,000,000 tons, while an equal quantity may be represented by other deposits that are not now workable by reason of their inaccessibility or other unfavorable circumstances.

Estimates of Adirondack ores.

	Available.	Not available.
	Long tons.	*Long tons.*
Nontitaniferous magnetites:		
High-grade ores	35,000,000	....
Concentrating ores (concentrates)	75,000,000	25,000,000
Titaniferous magnetites	90,000,000	100,000,000
Red hematites	2,000,000	2,000,000

(3) CLINTON ORES.

CHARACTER OF THE ORE.

The Clinton iron ore, so named from its typical occurrence at Clinton, N. Y., is an amorphous red hematite mixed with calcium carbonate, silica, aluminum silicate, and other minerals in minor quantities. It includes the varieties known as fossil ore and oolitic ore.

It occurs in lenticular beds analogous to the strata of sandstone, shale, and limestone, with which they are interbedded.

The fossil ore consists of aggregates of fossil organic remains in which the original calcium carbonate has been replaced partly or wholly by ferric oxide. The fossils, which consist of broken and waterworn fragments, were evidently gathered into beds by the action of waves and currents, and subsequently cemented together by calcium carbonate and ferric oxide. More or less clay material was also included in the beds during their deposition, and this now forms thin seams of shale.

The oolitic ore consists of aggregates of flat grains with rounded edges about the size and shape of flaxseeds. These grains generally lie parallel to the bedding planes of the rock, and the mass is cemented by ferric oxide and more or less calcium carbonate. The flattened grains have a nucleus of quartz, generally very minute, about which successive layers of iron oxide, and, in many instances, thin layers of amorphous silica and aluminous material, have been deposited. One of the two varieties of ore generally predominates in a bed, but in certain localities both fossil and oolitic materials are mixed in nearly equal proportions. The fossil ore, where unweathered, as compared with the oolitic ore in the same condition, is apt to be the more calcareous, while the oolitic ore may carry higher proportions of silica and alumina.

A characteristic of the Clinton ore is that where it has been weathered or acted upon by surface waters the lime carbonate is dissolved out, thereby increasing the content of iron oxide, silica, and other constituents proportionately. Such altered ore is termed "soft ore," and it is usually porous and friable as compared with the unaltered material, which is termed "hard ore." The alteration of the ore beds takes place at the outcrop and extends to varying depths from a few inches to 400 feet, depending on the attitude of the beds and on the thickness and permeability of the overlying rocks. The quantity of the soft ore is relatively small in comparison with the hard ore, and owing to its higher content of iron and its greater accessibility, a large part of the soft ore has already been mined.

In general the hard and semihard ores range in percentages of major constituents as follows: Metallic iron, 30 to 45 per cent; lime, 5 to 20 per cent; silica, 2 to 25 per cent; alumina, 2 to 5 per cent; magnesia, 1 to 3 per cent; phosphorus, 0.25 to 1.5 per cent; sulphur, a trace to 0.5 per cent; and water, 0.5 to 3 per cent. The ore is therefore of non-Bessemer grade. Small quantities of manganese are found in the Clinton ore in places, especially in the South. The content of this mineral seldom exceeds 0.25 per cent. In the soft ore the lime generally runs less than 1 per cent, so that the percentages of the other constituents are proportionately higher.

GEOLOGIC RELATIONS AND DISTRIBUTION.

The Clinton formation, of which the Clinton ore beds are a part, consists of lenticular, overlapping sedimentary beds, chiefly shale, sandstone, and limestone. In some places shale predominates, in others sandstone, and less commonly limestone. One or more iron-ore beds are generally present, although over considerable areas none occur.

The formation has a wide distribution in the eastern half of the United States. In the Mississippi Valley it is present in Wisconsin and Missouri, in the latter State having been recognized in a drill hole by the presence of a bed of iron ore over 8 feet thick at a depth of 2,000 feet. In eastern Wisconsin the formation is represented by a bed of iron ore only, which varies in thickness from 1.5 to 25 feet. In Ohio, Indiana, and northeastern Kentucky the formation occurs generally with thicknesses of 35 to 50 feet, but containing ore only in the latter State. In northern New York the Clinton rocks extend in a east-west strip from Niagara River to Otsego County. Here the thickness ranges from 32 to 295 feet. In all these States the beds are approximately horizontal or dip at very low angles. In the Appalachian belt from northern Pennsylvania southwestward to central Alabama the Clinton is a well-developed formation, and the beds are generally inclined at angles varying from 10° to 90°. The thickness of the formation decreases from 2,000 feet in Pennsylvania to about 850 feet in Virginia, 300 to 750 feet in Tennessee, and 200 to 700 feet in Alabama and Georgia.

While the total length of outcrop of all the areas of ore-bearing Clinton formation would reach several thousand miles, only a relatively small part of this outcrop contains ore workable under present conditions. The workability of an ore bed depends on its thickness, extent, composition, and attitude, and also upon its situation with respect to transportation routes, fuel, and markets. The first set of factors are of greatest importance, since few areas of good ore are so inaccessible that they will not sooner or later be reached by railroad. Local conditions also play an important part in determining the workability of an ore bed. For instance, in districts where several such beds occur in the formation, as in Alabama, only the thicker and richer ores are now worked, while others that would be at once exploited if they were in Pennsylvania are for the present neglected.

Wisconsin.—In Wisconsin Clinton ore has been produced in Dodge County since 1849. The ore occurs at Iron Ridge in an irregular lens-shaped bed between the "Cincinnati shale" and the Niagaran limestone. Its thickness varies from 1.5 to 25 feet. At other points, within a radius of 10 miles, the same ore bed occurs and it is known to thin out to the east. Toward the west the ore has been eroded, so that the outcrop lies in a westward-facing scarp about 60 feet high, capped by Niagaran limestone. Open-cut and underground mining have been carried on here. The ore as originally mined ran low in lime and contained about 45 per cent iron. It was partially hydrated and represented the "soft ore" of the outcrop. In 1906 the production of ore from Iron Ridge was nearly 90,000 tons, and in 1907 about 22,000 tons. Recent exploration work has proved that a considerable reserve of hard ore remains in this district, amounting to about 40,000,000 tons.

Kentucky.—A bed of Clinton ore, averaging probably more than 2 feet in thickness, occurs in Bath County, Ky., underlying an area of about 8 square miles. This ore lies nearly horizontal, but most of it is below too heavy cover to admit of mining under present conditions. It carries from 30 to 40 per cent iron and 13 to 16 per cent lime carbonate. At present the ore is mined by stripping where the cover is not more than 8 to 10 feet thick. The deposit has produced approximately 190,000 tons, and it is estimated that there are remaining 25,000,000 tons, one-tenth of which may be available under present conditions.

New York.—The belt of ore-bearing Clinton within New York State extends from Rochester on the west nearly to Utica on the east, a distance of about 130 miles. The width of outcrop of the formation reaches a maximum of 5 miles. The beds dip toward the south, from

45 to 80 feet to the mile. Conditions are extremely favorable for underground mining and should permit work to a distance of 3 to 5 miles from the outcrop wherever the ore is of sufficient thickness. The ore bed that is worked varies in thickness from 1.5 to 4 feet, with an average of about 2.5 feet. It carries 35 to 45 per cent of iron, with an average, where worked, of about 40 per cent. The phosphorus is high, from 0.25 to more than 1 per cent, and the sulphur, while variable, runs from traces up to 0.5 per cent. The ore has been worked in Wayne, Cayuga, and Oneida counties.

An estimate made by the New York State Survey of the tonnage contained in this district, mainly in these three counties, gives a total of 600,000,000 tons. Ore beds less than 1.5 feet thick and at a depth of more than 500 feet, as well as those carrying less than the average content of iron, have been excluded from consideration. Much of this ore, however, is not available under present conditions.

Pennsylvania.—The length of outcrop of the Clinton formation in Pennsylvania is very great owing to its repetition in the many anticlinal folds within the central part of the State. In the counties of Snyder, Mifflin, Juniata, Blair, Huntingdon, and Bedford, three or four thin beds of red ore occur, ranging in thickness from a few inches to more than 2 feet. The ore on the outcrop is usually soft and rich enough to work by stripping, but the hard ore under cover is in most places too thin to be worked at present. In a few places, however, where the beds are from 1 to 2 feet thick, underground drifts and slopes have been driven for short distances in the hard ore. The soft ore carries 40 to 50 per cent of iron and from a trace to 5 or 6 per cent of lime. The hard ore carries 20 to 35 per cent of iron, and in places as much as 25 per cent of lime.

Less than 20,000 tons a year of Clinton ore are now being produced in Pennsylvania, and it is probable that the reserves of this ore at present available in the State are not much in excess of 5,000,000 tons.

Virginia and north Tennessee.—The ore beds in the Clinton in Virginia are generally too thin to be considered important reserves after the soft ore shall have been mined out. In the west-central part of the State beds at Lowmoor range in thickness from 16 to 21 inches, and at Iron Gate from 8 to 12 inches. The soft ore carries 46 to 57 per cent of iron. Nearly 90,000 tons were shipped in 1907 from mines in this district, and at this rate of production most of the easily accessible soft ore will probably be exhausted within ten or twelve years.

The Clinton formation, outcropping along the foot of Cumberland Mountain, is ore-bearing from Cumberland Gap, Va., to La Follette, Tenn. Near Cumberland Gap there are three ore beds ranging in thickness from 6 inches to 2.5 feet. Only the upper bed, the thickness of which ranges from 15 to 20 inches, is workable. Southwestward toward La Follette the ore increases in thickness to 3.5 feet. Here practically all the soft ore has been mined out, so that only a hard ore, carrying 26 to 32 per cent of iron, remains. It is estimated that about 16,000,000 tons of such ore are still available in the Cumberland Gap-La Follette district.

It is possible that future exploration of the extensive areas of Clinton formation within Virginia and West Virginia may reveal additional ore reserves.

Rockwood-Chattanooga-Gadsden district.—This district embraces an area about 30 by 125 miles in the Appalachian valley region of east Tennessee, northwest Georgia, and northeast Alabama. Steeply dipping Clinton strata outcrop in narrow strips on both sides of Walden Ridge and Lookout Mountain and in the Whiteoak Ridge and other synclines of the Tennessee Valley. Ore is mined at North Chattanooga, Rockwood, Cardiff, Euchee, Welker, and Ooltewah, Tenn., and has been mined extensively at Inman. The important mining localities in Georgia are at Rising Fawn and Estelle, and in Alabama at Battelle, Portersville, Crudup, Attalla, and Gadsden.

The workable ore beds range from 2 to 5 feet in thickness and carry from 30 to 40 per cent of iron, 10 to 25 per cent of lime, and 0.5 to 0.7 per cent phosphorus. The use of much of the ore that is low in iron and high in lime depends upon the continuance of supplies of brown ore. The latter is mixed in the blast furnace with red ore that contains more than sufficient lime to be self-fluxing.

Estimates based upon fairly complete examinations place the available Clinton ore of the Rockwood-Chattanooga-Gadsden district at 86,570,000 tons, and the ore that will ultimately become available at 440,000,000 tons.

Birmingham district.—The Birmingham district includes the Clinton ore-bearing areas of Alabama from Springville southwest beyond Woodstock. As in Tennessee and Georgia, the Clinton formation in Alabama outcrops in narrow strips on the flanks of synclinal mountains. The dips range from 10° or 15° to vertical. The most important outcrop is along the crest of Red Mountain for about 25 miles near Birmingham. Other areas of minor importance occur along West Red Mountain near Birmingham. The thickness of the more important ore beds ranges from 2.5 to 12 feet. The ore carries from 30 to 40 per cent of iron, 10 to 25 per cent of lime, 0.3 to 0.6 per cent phosphorus, and from a trace to 0.1 per cent sulphur.

Estimates of tonnage of available ore for the Birmingham Clinton ore field indicate a supply of probably 358,470,000 tons, and of ore not at present available of about 438,000,000 tons.

SUMMARY AND ESTIMATES.

The Clinton formation has a wide distribution in the central and eastern portion of the United States, but contains commercially important ore beds in only a part of its area. The most important deposits are in the Birmingham, Chattanooga, and New York State districts, while less extensive deposits occur in Virginia, Wisconsin, Pennsylvania, and Kentucky.

It is evident from the above description that the quantity of ore contained in any area of the Clinton formation may be calculated with a fair degree of accuracy, provided sufficient data are available as to its dip and as to variations in thickness and quality of the ore beds. An assumption must be made as to depth-limiting workability under a variety of structural conditions, and since this is a matter of opinion it will vary somewhat widely and introduce corresponding differences in the results. Conditions of blast-furnace practice locally may define the quality of a workable ore. In places where brown ores are available for mixing with Clinton ores, an ore of the latter class can be used as a flux, although it runs so low in iron and so high in lime that alone it would not be acceptable. The estimates of available ores made by various experts do not, however, differ materially. In case of the total ore which is not now available, but which may be mined eventually, the variance in estimates is much greater, since more unknown factors enter into the problem.

The estimates given below are based upon detailed examinations of the more important districts by the United States Geological Survey for the Birmingham and Chattanooga districts, and by the State Survey for the New York district, with a study of all obtainable drill records.

Estimates of Clinton ores.

District.	Available.	Not available.
	Long tons.	*Long tons.*
Birmingham	358,470,000	438,000,000
Chattanooga	86,570,000	440,000,000
New York	30,000,000	570,000,000
Virginia-North Tennessee	16,000,000	50,000,000
Wisconsin	10,000,000	30,000,000
Pennsylvania	5,000,000	50,000,000
Kentucky-West Virginia	2,500,000	42,500,000

(4) APPALACHIAN METAMORPHIC ORES.

This group includes the deposits of magnetite and specular hematite associated with the crystalline and metamorphic rocks of the Piedmont and Appalachian mountain belts, which extend from southern New York to central Alabama. The ore deposits are not uniformly distributed throughout this area, but are confined to certain portions where geologic conditions have been favorable for their accumulation. The most important districts are (1) the highlands of southern New York and northern New Jersey; (2) the James River district, Virginia; (3) the Cranberry district, North Carolina; (4) the Piedmont district, North Carolina; (5) the Yorkville district, South Carolina; (6) the Talladega gray ore district, Alabama. The last-named district is included in this group for convenience, although it differs materially in its geologic relations from the others.

The ore deposits of this group have the form of lenticular beds or elongated pods, which are interlaminated with the gneisses, schists, or crystalline limestones. The individual deposits vary in thickness from a fraction of an inch up to 50 or even 80 feet, but the majority of the workable deposits are from 4 to 15 feet thick and are apt to show rapid variations by pinching and swelling on both the strike and the dip. They vary in composition from practically pure iron ore to a material containing a large proportion of gangue minerals. In general, the larger deposits contain the smaller proportion of iron and can be worked only by the employment of some method of concentration.

The deposits rarely occur singly, but are more often disposed in rather narrow belts separated by wider belts of barren gneiss and schist. Since the ores were undoubtedly derived from a deep-seated source, there is no reason to anticipate a failure in depth, although pinches and swells are to be expected in the course of deep mining, and the cost of mining will necessarily increase with depth.

The gray hematites of the Talladega district and certain hematite deposits of Virginia and Georgia are here included for convenience, though they occur under entirely different geologic conditions from those above described. These hematites have the appearance of regularly bedded deposits, associated with sedimentary rocks which have suffered only slight metamorphism. Whether or not they were deposited at the same time as the inclosing sediments has not been definitely determined. They possess much greater uniformity, both on the dip and along the strike, than the magnetites in the crystalline rocks, and for practical purposes may be regarded as original bedded deposits.

In view of the irregularities in thickness of the magnetite beds, which can not be determined in advance of thorough prospecting, it is impossible to make any accurate calculation of the amount of ore which they contain even when their area at the surface is known, and this is rarely the case. The following estimates, therefore, are only approximate, particularly the amount assigned to the nonavailable class:

Estimates of Appalachian metamorphic ores.

Ores.	Available.	Not available.
	Long tons.	*Long tons.*
Magnetites, including some titaniferous magnetites and some hematite	47,500,000	74,500,000
Specular hematites, including some limonites	8,000,000	53,000,000

(5) APPALACHIAN BROWN ORES.

This group embraces those deposits of brown ores associated with the Appalachian belt of closely folded sedimentary rocks which extends continuously from northern Vermont southwestward to central Alabama. It is bounded on the east by the older crystalline and metamorphic rocks of the Appalachian Mountains, and on the west by the younger "Coal Measures." It is underlain by limestones, dolomites, shales, sandstones, and quartzites, ranging in age from Cambrian to Carboniferous. The beds, originally deposited in approximately horizontal layers, have been folded and faulted so that they now occupy all possible attitudes. This has given rise to conditions favorable to the rapid weathering of the rocks. The steeply dipping sandstones and quartzites form sharp ridges, while the more easily eroded limestones, dolomites, and shales form the intervening valleys, their surfaces being generally covered with a deep mantle of residual materials. These rocks, particularly the shales and some of the limestones, contain small quantities of iron minerals, sulphides, carbonates, and silicates, and in the process of weathering and erosion, by which many thousand feet of strata have been removed, the iron originally contained in these widely disseminated minerals has been concentrated, where conditions were favorable, as the hydrated oxide forming the deposits of brown ore. These deposits, while presenting great diversity in form, fall into three classes, known as mountain ores, valley or limestone ores, and Oriskany ores.

MOUNTAIN ORES.

These deposits are so called because they always occur upon the flanks or at the base of a sandstone, chert, or quartzite ridge, and throughout Virginia, Tennessee, Georgia, and Alabama they are most extensively developed along the extreme eastern margin of the valley belt where the Cambrian quartzite forms a high ridge flanking the crystalline rocks. The quartzite beds dip steeply beneath the overlying shales and limestones, and iron derived from the latter during the process of weathering has been concentrated downward upon this impermeable foot wall. Similar conditions favorable for ore concentration occur elsewhere in the Appalachian belt where the Cambrian quartzite in isolated ridges dips beneath the overlying shales, as at Anniston, Ala., and also at a few points where the lower Carboniferous chert has formed an impermeable foot wall, as at Sugar Valley, Ga. The deposits present great diversity in form, varying from fissure veins and replacement zones in the sandstone and shale, through blanket deposits resting on the quartzite, to irregular pockets scattered through the residual clay. The last are the most abundant and characteristic. Their size can rarely be determined in advance of development, even by systematic prospecting, and estimates of their available tonnage vary between wide limits.

VALLEY OR LIMESTONE ORES.

These are associated with the great limestone and dolomite formations which underlie much of the Appalachian belt. They are also derived from the iron minerals originally disseminated through the rocks and have been concentrated during the process of weathering and erosion. Their location depends on the original abundance of these minerals in the rocks and on favorable conditions for concentration afforded during erosion, in some cases probably by the fracturing of the beds and the consequent free underground circulation of water, and in others by the location of an easily soluble bed of limestone toward which drainage from surrounding areas brought the iron and deposited it as bog ore. They are always embedded in the residual mantle composed of the insoluble portions of the underlying rocks. The deposits vary in form, but generally consist of concretionary masses ranging in size from those containing several tons down to pellets the size of a pea, disseminated through the residual clay.

ORISKANY ORES.

These deposits are more regular in their occurrence, being limited to a definite horizon in the Helderberg limestone immediately beneath the Oriskany sandstone. They are confined to a comparatively small portion of the valley belt, chiefly in southwestern Virginia with a few deposits in Pennsylvania and West Virginia. The iron was originally disseminated in the overlying shales, and wherever these shales occurred in sufficient thickness and the limestone bed occupied a favorable attitude its lime carbonate has been replaced by the iron oxide for a greater or less distance below the surface. The deposits frequently extend continuously for several miles along the outcrop, being made up of a series of lenses which may reach 75 feet in their thickest portions and thin down to a foot or less where adjacent lenses come together. The greatest depth to which the ore has been found is about 600 feet. Where the replacement has been complete and extensive, therefore, it has the form of a bedded deposit and the ore content can be estimated with some certainty. The deposits consist either of fairly solid ore or of irregular masses and seams of ore embedded in clay.

DEVELOPMENT AND ESTIMATES.

The Oriskany deposits are mined both by stripping on the outcrop and by regular underground mining. The mountain and valley ores are nearly always mined in open pits, in the larger operations by steam shovel, and in a few cases by the hydraulic method. Where hand mining is done, a part of the ore is sent direct to the furnace without other treatment than hand picking, but where the steam shovel is used everything is passed through the washer. In most cases sorting tables and jigs are employed in addition to the washer. By these means the associated materials, consisting of clay, chert, and other rock fragments, are removed from the ore. The average iron content of the ore as shipped is about 45 per cent, and the phosphorus is generally above the Bessemer limit. The deposits of this group, being widely disseminated and easily mined in open pits, furnished a large part of the ores used by the small charcoal furnaces in the early development of the iron industry in the United States. With increase in capacity of furnaces a more reliable ore supply has been sought, and many districts which were formerly heavy producers have been temporarily abandoned. The ore is still in demand, however, chiefly for mixture with the calcareous Clinton ores, and its production will doubtless increase in the future beyond any point previously reached.

From the above description of these brown-ore deposits it will be readily understood that extreme difficulty must attend any attempt to estimate their total tonnage. It is unsafe to base an estimate on the number of known occurrences of the ore multiplied by an average content derived from the known yield of certain deposits which have been worked out, for the best deposits are the ones most apt to be exploited first. The estimates given below are based in part on systematic examination and measurement of all known deposits in certain districts and in part on general considerations of distribution and geologic occurrence. The amounts given in the second column of the table, representing ore not now available, are confessedly little better than guesses and future exploration may show them to be much too low. It should be stated further that estimates made by competent experts differ from the figures here given by a factor varying from 0.7 to 3.

Estimates of Appalachian brown ores.

	Available.	Not available.
	Long tons.	*Long tons.*
New England and New York	1,000,000	1,500,000
Pennsylvania, Maryland, and New Jersey	10,000,000	12,000,000
Virginia, West Virginia, and East Tennessee	35,150,000	136,000,000
Alabama, Georgia, and North Carolina	19,250,000	32,000,000

(6) APPALACHIAN CARBONATE ORES.

This group of deposits includes the beds of carbonate ores and their oxidized outcrops which occur in the Carboniferous rocks within a broad belt stretching from western Pennsylvania through Ohio into northeastern Kentucky, and probably extending also into Tennessee and Alabama. The rocks occupying this belt are chiefly sandstones and shales, with occasional thin beds of limestone. The beds are nearly horizontal, and the topography is such that the outcrop of any stratum is extremely sinuous and may have a length many times the shortest distance between two points. This combination of structure and topography has an important bearing on the possible utilization of the iron ore.

The group embraces several varieties of ore locally distinguished as limestone ore, block ore, kidney ore, and black-band ore, each of which is accompanied by a corresponding variety of oxidation product. All of the varieties are non-Bessemer ores. The limestone ores are associated with thin beds of limestone, the most widely distributed being the Vanport and Maxville. The ore beds lie immediately above the limestones, which they sometimes entirely replace. They are usually only a few inches thick, but occasionally expand to several feet. For varying distances from the outcrop the original iron carbonate has been oxidized to a dense brown ore, with loss of carbonic acid and increase in proportion of iron. The unaltered carbonate contains 30 to 35 per cent iron, and the alteration product from 43 to 47 per cent.

The block ores are fairly regular bands of iron carbonate, interstratified with shale or fine sandstone. They are more persistent and uniform in thickness than the other varieties. In Kentucky three persistent beds are recognized having a total outcrop of over 450 miles. The quality of the ore varies inversely with the thickness of the beds, the thinnest beds carrying the best ore. The unaltered carbonate carries from 29 to 34 per cent iron, and the brown ore on the outcrop from 33 to 43 per cent.

The kidney ores, as their name implies, are concretionary in form and occur in certain beds of clay shale, rarely forming continuous layers. They grade into the black-band ores, which are usually more or less closely associated with coal beds and contain carbonaceous matter which gives them a black color. These concretionary forms generally contain the purest iron carbonate and on oxidation at their outcrop yield a correspondingly pure limonite, or brown ore.

In the early history of iron making in the United States this ore belt in Pennsylvania, Ohio, and Kentucky contained a large number of small charcoal furnaces and the aggregate amount of ore produced was very considerable. With the disappearance of the forests the iron industry in this region declined, and the use of these ores has practically ceased. The production was confined largely to the oxidized surface ores, which not only were more easily accessible but gave the best results in the primitive furnaces. While the deposits of this group contain a large aggregate tonnage, practically all of it must be classed as not at present available. The principal reason that the ore can not now be worked at a profit is the fact that the nature of the deposits does not permit operations on a large scale. At only a few points are the beds sufficiently thick and persistent for underground mining, and stripping is therefore the method used. The distance which stripping can be carried into the hillside depends on the slope and the thickness of the bed. An average width of the belt from which the ore can be mined has been assumed as 100 feet, and the average thickness of the ore bed from 10 to 12 inches. The aggregate length of outcrop of the several ore beds has been taken as follows: For Pennsylvania, 866 miles; Ohio, 2,056 miles; and Kentucky, 1,260 miles. With these assumptions the total tonnage of carbonate and associated limonite ores which may ultimately be produced in these three States, and in Tennessee and Alabama, is as follows:

Estimates of Appalachian carbonate ores.

	Available.	Not available.
	Long tons.	*Long tons.*
Pennsylvania		46,000,000
Ohio		200,000,000
Kentucky		60,000,000
Tennessee-Alabama		2,000,000

(7) WEST TENNESSEE BROWN ORES.

This group embraces the ore deposits within a broad belt extending from the northern border of Alabama and Mississippi across western Tennessee and Kentucky. This region is a plateau of moderate elevation which has been dissected by the Tennessee River and its tributaries. The rocks underlying the ore-bearing territory are lower Carboniferous cherty limestones. The ore deposits closely resemble the limestone ores of the Appalachian Valley. They vary in size from scattered concretions embedded in surface cherty clay to bodies having a depth of 120 feet or more and containing upward of half a million tons. The larger deposits are confined to slight depressions in the plateau surface, in which deposits of waterworn bowlders suggest the former presence of streams. The ore was doubtless derived from the accumulation during the process of weathering and erosion of iron contained in minerals disseminated through the higher formations. These ores have been mined for many years, supplying a number of local charcoal furnaces and being shipped for mixture with the calcareous Clinton ores of the Chattanooga and Birmingham districts.

In the absence of detailed examination of this ore belt, estimates of ore tonnage contained in these deposits must rest upon a very small foundation of ascertained fact. A few of the deposits have been studied, as those at Russellville, Mannie, and Goodrich, and the estimates for the entire district are based upon these disconnected observations. These estimates place the available ore at 10,000,000 tons, and the ore not now available, chiefly because of the excessive cost of transportation and of working scattered deposits, at 15,000,000 tons.

(8) EAST TEXAS BROWN ORES.

This group of deposits occurs in the northeastern portion of Texas and the adjacent portions of Louisiana and Arkansas. They differ materially in their geologic relations and in the problems of utilization from the brown ores previously described. The region is underlain by Tertiary formations, chiefly unconsolidated sands, clays, and greensands. The ore forms a fairly uniform layer, rarely averaging over 2 feet in thickness, and covering large areas. It is at places exposed at the surface and elsewhere covered by soil and sand to a depth of 6 feet or more. The ore averages about 46 per cent of iron, and is above the Bessemer limit in phosphorus. It is generally high in both silica and alumina. The deposits are probably derived from the oxidation in place of beds and nodules of iron carbonate, although it may be in part due to the concentration of iron derived from the greensand and other iron minerals disseminated through adjacent formations. While these deposits contain in the aggregate a large amount of ore of fairly good grade, its utilization presents somewhat serious difficulties. Owing to the thinness of the deposits the ore can not be excavated with steam shovel or other mechanical devices. The scarcity of water in the region will prevent hydraulicking and also economical washing of the ore, so that only the lump ore can be utilized.

These deposits have been mined at a number of points and have supplied a local furnace for some years. The same region is underlain by beds of lignite, one of which at a depth of about 50 feet has a thickness of over 4 feet. Should it prove practicable to use this lignite in blast-furnace practice, directly or as a gas producer, its occurrence in the immediate vicinity of the ores would prove highly advantageous in their utilization.

In the absence of detailed surveys it is not possible to closely estimate the area of the workable deposits. The total area known to be underlain by the ore-bearing formation is about 500 square miles, and of this probably 50 square miles contain a bed averaging 2 feet in thickness, which is taken as the limit of profitable working at the present time. Upon this basis the district is estimated to contain 260,000,000 tons of available ore, and it is probable that it contains twice this amount of ore that is not now available but will be utilized eventually.

(9) OZARK ORES.

[Based on reports of the Missouri State Survey.]

The Ozark district embraces the southern half of Missouri and a narrow strip along the northern border of Arkansas. It consists of a broad, unsymmetrical, domelike uplift, by which the older rocks are brought to the surface near the center of the district and, dipping outward in all directions, pass under successively younger formations toward its circumference. The oldest rocks in the district are igneous, porphyry and granite, on the irregularly eroded surface of which the Cambrian formations were deposited. The greater part of the district is occupied by cherty, magnesian limestone, with subordinate sandstones and shales.

The district contains four classes of iron ores in deposits of sufficient size to be of commercial importance. These are (1) coarse specular hematite, occurring in veins in porphyry and in associated conglomerate beds; (2) fine specular hematite, occurring in pockets at the contact between Cambrian sandstones and limestones; (3) brown ore, limonite, occurring in pockets in the residual clay and chert derived from the weathering of limestones; and (4) red hematite, occurring as bedded deposits with Carboniferous shales and sandstones. In addition the "Coal Measures" contain occasional thin beds of iron carbonate, but these are not known in deposits of commercial size. Each of these classes of ore being associated with certain geologic formations, their distribution is dependent on the structure of the district. The porphyry ores are confined to a small district in Iron County, practically to the two localities, Iron Mountain and Pilot Knob. The fine hematites are grouped within an area about 50 miles in diameter, chiefly in Phelps and Crawford counties, where the Roubidoux sandstone occupies the surface. The limonite deposits form two irregular groups, the first occupying the basin of the Osage River and the second extending along the southeastern margin of the district. The deposits of the red hematite are less numerous than the other kinds, and occur chiefly along the northern margin of the district.

SPECULAR PORPHYRY HEMATITE.

The interest in these deposits is chiefly historic, since they are now practically exhausted and thorough testing in the most favorable localities has entirely failed to reveal additional deposits. These were the first iron ores worked west of the Mississippi River and supplied several local furnaces, the first of which was built about 1815. They continued to produce up to 1893 and have had a total production of 4,500,000 tons. The history of the development and exhaustion of these deposits is instructive as illustrating the fallacy of the popular belief that many ore bodies are inexhaustible and showing that they are very definitely limited in the amount of ore which they will yield.

SPECULAR SANDSTONE HEMATITE.

These deposits consist of irregularly circular pockets from 300 to 500 feet in diameter, located in the sandstone and extending downward into the underlying limestone. The ore occurs both as bowlders mixed with fragments of sandstone, chert, and residual clay and as a solid, indistinctly bedded mass. The unaltered ore is a dense, fine-grained blue or gray hematite, which near the surface has been changed largely to soft red hematite or to limonite. The better grades contain 55 to 67 per cent of iron and are generally low in phosphorus. In addition there are large amounts of siliceous ore which are not available under present conditions. The yield of individual deposits may be in excess of half a million tons, and unless erosion has cut into deposits of this size they may afford little or no indication of their presence at the surface. In the absence of thorough testing, surface indications are therefore unreliable as a basis for estimates of the ore content of these deposits. A large amount of uncertainty must be present in any estimate of total tonnage, and the figures given are regarded only as roughly approximate. These deposits at present form the chief source of iron-ore production in the Ozark district.

BROWN ORES.

Deposits of this class occur in very large numbers as irregular pockets in the residual material overlying various limestone formations. They are due to the concentration of iron contained in minerals originally disseminated through the rocks which have been removed and were concentrated during the process of weathering and erosion. They are in part also derived from the solution and redeposition at lower levels of other iron ores, as the specular and red hematites. Over 500 localities are listed at which these deposits occur, and while they vary widely in the amount of ore contained, the aggregate tonnage must be very considerable. Owing to the small size of many of these deposits, their distances from transportation places them in the class of ores not at present available. Also, in a considerable proportion of the deposits, the ratio of ore to clay is too low for profitable working at present.

RED HEMATITE.

These ores occur as regularly bedded deposits in certain portions of the lower Carboniferous formations along the northern border of the Ozark district. They are variable in thickness and horizontal extent. The deposits are practically undeveloped, and owing to the low grade of the ore and the thinness and variability of the beds, they can not at present compete with other ores of higher grade and more cheaply mined.

SUMMARY.

The estimates of tonnage contained in the various classes of ore deposits in the Ozark district are summarized in the following table:

Estimates of Ozark ores.

	Available.	Not available.
	Long tons.	*Long tons.*
Sandstone hematite	15,000,000	5,000,000
Brown ore	30,000,000	45,000,000
Red hematite	....	5,000,000

(10) ROCKY MOUNTAIN METAMORPHIC ORES.

This group embraces the deposits of magnetite and specular hematite associated with crystalline schists and gneisses at various localities in the Rocky Mountain region. They are similar in most particulars to the deposits of the same ores in the crystalline metamorphic belt of the Eastern States. They consist of lenticular beds conforming in dip and strike to the foliation of the inclosing rocks and varying greatly in thickness within short distances, both in depth and along the outcrop. Associated with these beds, and evidently derived from them, are occasionally found secondary fragmental deposits, which are sometimes overlain by later sedimentary or igneous formations.

The best-known deposits of this group occur in the Hartville district, Wyoming, and in the Llano district, Texas. They also occur at various points in Colorado, Nevada, New Mexico, and Arizona, and in general may be expected wherever there are considerable areas of crystalline gneisses and schists. They have been extensively worked in the Hartville district, supplying a part of the ore for the furnaces at Pueblo, Colo., and being used also to some extent for fluxing silver ores. It is probable that a much larger proportion of the deposits of this group are as yet undiscovered than of any other group of iron-ore deposits. In view of the extremely meager information, estimates of their contents have little value. The ore is generally high grade, though sometimes siliceous, but a large proportion of the deposits are not at present available by reason of remoteness from transportation lines and distance from suitable fuel for their reduction.

(11) IGNEOUS CONTACT ORES.

This group is based exclusively upon its geologic relations, and the deposits are widely distributed, though the most of them are located in the Rocky Mountain and Pacific States. The essential characteristics of the deposits are the following: They are steeply dipping, lens-shaped bodies, which closely follow the contact of an intrusive igneous mass and an intruded limestone. They occur partly within the igneous rock as dikelike veins and partly within the limestone, but generally at the immediate contact. The limestone is always altered for a variable distance, sometimes several hundred feet from the contact, the alteration consisting in extreme silicification and the development of lime-bearing metamorphic minerals. The ores are magnetite, or more generally an intimate mixture of magnetite and hematite. They are often altered at the surface to red hematite and to some extent to limonite. The original bedding planes of the limestone are sometimes preserved in the ore body. The gangue consists of quartz and aluminous silicates, in part the recrystallized impurities of the limestone and in part minerals introduced along with the iron. The ores are believed to be due to hot solutions rising from a deep-seated source through fissures in the igneous rock at a period closely following its complete or partial solidification.

CORNWALL DISTRICT, PENNSYLVANIA.

The principal eastern representative of this group is in eastern Pennsylvania, where the ore, chiefly magnetite, has been mined since the early part of the eighteenth century. These deposits, of which the Cornwall mine is considered the type, occur at the contact of intrusive masses of Mesozoic diabase and Cambrian limestone. The more easily accessible portions of the deposits have been mined out, but they are estimated to contain 50,000,000 tons of ore, of which about 15,000,000 tons are considered available under present conditions.

IRON SPRINGS DISTRICT, UTAH.

These are the best known of the western representatives of the group. They are located in southwestern Utah, about 250 miles from Salt Lake. The ore, which consists of both magnetite and specular hematite (70 per cent of the former and 30 per cent of the latter), occurs at or near the contact of laccolithic intrusions of andesite in Carboniferous limestone. The aggregate surface of the known ore bodies is 5,430,000 square feet, and the calculated tonnage to a depth of 130 feet is 40,000,000 tons. While this is the greatest depth at which the ore has been actually observed in prospect pits, a careful consideration of its geologic relations leads to the conclusion that it extends to considerably greater depths, and probably twice the above tonnage may be taken as the amount which is present but not now available. Practically no development has taken place except the sinking of a large number of prospect pits.

OTHER DISTRICTS.

Ore deposits belonging to this group are known to occur at numerous localities throughout the West, but they have not generally been examined in sufficient detail to permit accurate estimates of tonnage being made.

In Utah deposits occur at Bull Valley, about 25 miles southwest of the Iron Springs district and under similar geologic conditions. In California they are found in the Cave Canyon and other districts in San Bernardino County, in the Eagle Mountain district, Riverside County, in Shasta County, and elsewhere. In Nevada large deposits, estimated to contain at least 7,000,000 tons of magnetite and hematite, averaging 63 per cent of iron, are reported to occur in the Lovelocks district, in Humboldt and Churchill counties. Deposits also occur in Lyon County. In Washington deposits which probably belong to this group, although their relations are not known in detail, occur at a number of localities in the northeastern part of the State, in Stevens County. The ores are chiefly magnetite and hematite, though in part altered to limonite.

In Colorado iron-ore deposits occur near Ashcroft, in Pitkin and Gunnison counties, and in the White Pine and Cebolla districts, in Gunnison County. Those of the Ashcroft district occur on both sides of the Elk Mountains, at elevations between 11,000 and 12,000 feet above tide. The deposits are associated with limestones and igneous intrusives. They are of considerable size, the one on the northwest side of the divide being at least 300 feet on the strike and from 40 to 122 feet thick. Its total depth is not known, but it is proved to be at least 100 feet. The greater part of the ore is high in iron and sulphur, but low in phosphorus.

In New Mexico iron-ore deposits occur at Chupadera Mesa and at Fierro, in Grant County. The latter locality has been worked for some years, furnishing a large amount of ore for the Pueblo furnaces. The ore is associated with limestones and igneous intrusions, forming lenses at or near the contact between the two. It is accompanied with metamorphic minerals, as epidote and garnet, which are developed in the contact zone in great abundance. The ore is magnetite with subordinate amounts of hematite, and usually contains a small amount of copper. The greater part of the easily accessible high-grade ore has been mined out.

COMMERCIAL CLASSIFICATION AND SUMMARY OF ESTIMATES.

While the foregoing classification and grouping of the iron-ore deposits is a convenient one for purposes of description and for discussion of the basis and value of tonnage estimates, the grouping does not correspond with commercial conditions, and the estimates already given are therefore summarized by commercial grades and districts in the following table:

Estimates of iron-ore supplies of the United States.

2. Virginia, West Virginia, eastern Kentucky, North Carolina, South Carolina, Georgia, Alabama, east Tennessee.
3. Michigan, Minnesota, Wisconsin.
4. Northwest Alabama, west Tennessee, west Kentucky, Iowa, Missouri, Arkansas, east Texas.
5. Montana, Idaho, Wyoming, Colorado, Utah, Nevada, New Mexico, west Texas, Arizona.
6. Washington, Oregon, California.

FOREIGN IRON-ORE SUPPLIES.

In addition to the ore supplies included in the table given above, certain foreign deposits are so situated that they must depend, at least to a considerable extent, upon the American market, and are therefore to be considered practically a part of the available reserves. The most important of these sources of foreign supply are located in Canada, Newfoundland, Cuba, and Mexico. None of these countries has an abundant fuel supply, and therefore either the fuel must be imported or the ore exported. The history of the iron industry indicates that the latter is most likely to occur, particularly when the industry is already established and the chief market for the finished product is near the fuel supply. This tendency may be interrupted by artificial means, such as bonuses and tariffs, but such interference with the natural course of industrial development is only temporary, and in the long run the industry will gravitate to the point of the lowest cost of production.

CANADIAN ORES.

Recent explorations have shown the existence of considerable areas of the iron-bearing formations on the north shore of Lake Superior. The total tonnage of the iron formation in the Animikie, Michipicoten, and other north-shore districts is calculated at 93,600,000,000 tons. If the same proportion of this total be considered low-grade ore as in the Michigan and Minnesota districts it will amount to about 20,000,000,000 tons. Since these north-shore districts are not as yet thoroughly prospected, the ratio between high and low grade ores can not be definitely determined, but it is almost certainly much lower than in the Michigan and Minnesota districts. The best estimate of ore now available in these Canadian districts is 9,000,000 tons.

Deposits of iron ore of the igneous contact type are known to occur in British Columbia, and those on Texada Island have been mined to some extent. These deposits are estimated to contain at least 30,000,000 tons of ore of present commercial grade and probably a considerably larger amount of low-grade and deep ore not now available.

NEWFOUNDLAND ORES.

The most important of these are Clinton ores occurring on Belle Isle. Their area is definitely known and the doubtful factors are the proportion of ore below present commercial grade and the amount of available ore in beds known to extend under the ocean. The supply of available ore has been estimated at 30,000,000 tons, and the amount not now available may be several times this amount.

MEXICAN ORES.

Large deposits of iron ore are known to occur in various parts of Mexico. They are chiefly of the igneous contact and gossan types, and no estimate of any value can be made of their available tonnage. Remoteness from centers of iron production will prevent their extensive exploitation for the present, and they are therefore to be regarded as wholly within the unavailable class.

CUBAN ORES.

By far the most important foreign source of iron ore, measured by the extent of the supplies and their accessibility, is Cuba. The deposits are of two kinds, specular hematites of the Santiago district and brown limonites of the Mayari, Moa, Baracoa, Cubitas, and Pinar del Rio districts. The hematites have been worked extensively since 1884, and for a number of years have furnished more than 50 per cent of the total iron-ore imports. They are estimated to contain about 9,000,000 tons of ore, about half of which is actually measured.

The limonites are widespread residual deposits derived from the weathering of igneous rocks. The ore contains from 43 to 52 per cent of iron, phosphorus below the Bessemer limit, and between 1 and 2 per cent of chromium. These deposits are as yet practically undeveloped, but the more important ones have been fairly well prospected, and it is estimated that they contain an aggregate of 3,000,000,000 tons, at least one-third and possibly one-half of which may be regarded as now available. Most of the deposits are located near the northern coast of the island, so that they have the advantage of cheap water transportation to all parts of the Atlantic seaboard. They are without question destined to play an important rôle in the iron industry of the United States.

SUMMARY OF FOREIGN SUPPLIES.

The total estimated foreign supplies of ore sufficiently high-grade and accessible to mining and transportation to be at present available, and so located as to affect the iron industry of the United States, are shown in the following table:

Estimated foreign iron ores.

	Long tons.
Canada:	
British Columbia, magnetite chiefly	30,000,000
Lake Superior district, hematite chiefly	9,000,000
Nova Scotia, Clinton hematite	4,000,000
Newfoundland, Clinton hematite	30,000,000
Cuba:	
Santiago district, hematite	5,000,000
Mayari, Moa, Baracoa, Cubitas, and Pinar del Rio districts (limonite)	1,500,000,000
Total	1,578,000,000

IMPORTS AND EXPORTS.

The total imports of iron ore since 1889 have been 3 per cent of the domestic production for the same period. They have shown great annual fluctuations, responding quickly to changes in industrial conditions. Since 1904 there has been a steady and rapid increase in imports, and this increase may be expected to continue in the future even more rapidly with the expanding development of the Cuban limonite deposits.

The extent to which foreign ores are now supplying the market is shown by the following table of imports:

Imports of iron ore from foreign countries, 1889–1907.

Year.	Cuba.	Newfoundland and Labrador.	Quebec, Ontario, etc.	Spain.	Other countries.[a]	Total.
	Long tons.	*Long tons.*	*Long tons.*	*Long tons.*	*Long tons.*	*Long tons.*
1889	243,255	14,450	4,091	298,568	293,209	853,573

1897	383,820	29,250	....	66,193	10,707	489,970
1898	165,623	....	....	13,335	8,250	187,208
1899	360,813	77,970	....	145,206	90,093	674,082
1900	431,265	140,535	5,588	253,694	66,749	897,831
1901	526,583	[b] 79,360	163,383	180,810	16,814	966,950
1902	696,375	81,920	203,824	153,527	29,824	1,165,470
1903	613,585	[b] 86,730	169,681	94,720	15,724	980,440
1904	364,630	5,400	77,887	36,810	2,886	487,613
1905	539,935	5,600	104,096	191,861	4,159	845,651
1906	639,362	[b] 125,395	57,890	171,870	65,873	1,060,390
1907	657,133	89,685	26,878	296,318	159,154	1,229,168
Total	7,776,305	[a] 763,415	847,076	3,290,006	2,029,040	14,705,842

[a] Belgium, Brazil, British Columbia, England, France, French Africa, French West Indies, Germany, Greece, Italy, Mexico, Netherlands, New Brunswick, Norway, Nova Scotia, Oceania, Portugal, Sweden, Turkey in Asia, Turkey in Europe, Venezuela, etc.
[b] Includes Newfoundland only.

The exportation of iron ores has fortunately never assumed large proportions, as shown by the following table:

Exports of iron ore from the United States, 1899–1907.

Year.	Quantity.	Value.
	Long tons.	
1899	40,665	$76,297
1900	31,460	154,766
1901	64,703	163,465
1902	88,445	294,108
1903	80,611	255,728
1904	213,865	458,823
1905	208,017	530,457
1906	265,240	771,839
1907	278,208	763,422
Total	1,271,214	3,468,945

This export consists chiefly of Lake Superior ores shipped to Canadian furnaces for mixture with local ores. It contains also some high-phosphorus ores from the Adirondack district shipped to Germany. This movement has practically ceased, owing to increased home demand for these ores.

WASTE IN MINING AND REDUCTION.

Where iron ore occurs in the form of bedded deposits and is mined underground, waste is apt to occur from the same causes as in coal mining. These are the leaving of pillars to support the roof, often unnecessarily large, the leaving of low-grade ore in the mine where it can subsequently be recovered only with difficulty, if at all, and the breaking down of an overlying bed where the lower of two beds in the same territory is mined first. These sources of waste are confined largely to the Clinton ores, and the available facts are insufficient for closely estimating its amount, but the proportion of recovery varies with local conditions between 75 and 90 per cent and is undoubtedly increasing with improvement in mining methods. In computing the available tonnage of the Clinton ores an average recovery of 75 per cent has been assumed. Portions of the Clinton ore beds at present considered of no value because of shale partings and consequently left in the ground might be mined at many points if the shale could be separated from the ore economically. Improvement in cleaning and concentrating methods will undoubtedly make the recovery of much ore of this character possible. In the steeply dipping magnetite and hematite beds practically all ore up to the required grade is mined out, and the ground is generally left in such condition that the mines can be reopened for the recovery of lower-grade ores.

In surface workings waste is confined largely to small operations where quick returns are required, and systematic development is impossible. In such cases much ore is lost by dumping barren strippings and low-grade ore together, so that it can be recovered only with difficulty, if at all. Where the operations are on a large enough scale to warrant the installation of mechanical excavators, and a proper ore-dressing plant, this waste does not occur and practically all the ore in a deposit is recovered. Some waste of finely divided ore occurs in the process of washing brown ores to remove the associated clay, and there is still room for improvement in operations of this kind. If it becomes necessary to mine material which is below the grade of present requirements, but which contains enough iron values to make it a possible ore in the future, such material is stacked so that it will be available at any future time. This policy has been most consistently followed in the Lake Superior district, and when such low-grade ores are required large amounts will be available merely at the cost of loading on the cars.

In the early days of iron making an appreciable part of the iron in the ores went into the slag and was permanently lost. Blast-furnace practice, however, has been so greatly improved in recent years that this source of waste is eliminated and practically all of the iron in the ore is now recovered.

PRODUCTION AND USE OF IRON ORES.

The beginning of the iron industry in America dates from 1645, when a furnace and forge were built at Lynn, in the province of Massachusetts Bay. In the century following a large number of small furnaces and bloomeries were operated in the New England colonies, using bog ores almost exclusively, and during this period Massachusetts was the chief iron producer. In 1734 the richer brown ores of western Connecticut and southern New York were opened and largely replaced the bog ores. The manufacture of iron was begun in eastern Pennsylvania in 1716, and a few years later in northern New Jersey, using the rich magnetites of that region. The industry had a rapid growth, notwithstanding the restriction placed upon it, and at the time of the Revolution there were over 140 furnaces and bloomeries in operation in this district.

In the fifty years preceding the Revolution a number of furnaces and forges were in operation in Maryland, Virginia, and the Carolinas, located for the most part on the tide-water streams of the coastal plain and using the brown ores associated in small quantities with the clays and sands of the coastal formations. The deposits of magnetite in the crystalline rocks of the Piedmont were also worked during this period to a slight extent.

After the close of the Revolution the iron industry expanded rapidly, following the westward progress of settlement, and had reached western Pennsylvania and the Appalachian Valley of Virginia and Tennessee before the close of the eighteenth century. In the first third of the nineteenth century it had reached as far west as Missouri and north to Michigan. During this period conditions favored a wide distribution of the industry. Charcoal was the only fuel used, and this could always be obtained in the immediate vicinity of the ores. Transportation facilities were very poor, and the small furnaces so situated as to supply the local demand, even working on inferior ores, could compete with the older establishments at a distance. About 1840 a revolution was effected in the iron-making industry by the introduction of anthracite and bituminous coal as a furnace fuel. The capacity of the furnaces was rapidly increased, and with improvement in transportation facilities the industry was concentrated at a relatively few points advantageously located with reference to the new fuel supply. Under the changed conditions the ore was brought to the fuel, hence only the best ore and the largest deposits were worked, and many districts, as Ohio and Kentucky, which had been heavy producers, were practically abandoned. With the decrease in average iron content of ores going into the furnaces, due to the depletion of the richest deposits, there is at present a notable tendency toward decentralization of the industry and a consequent reopening of abandoned ore deposits, though it will never revert to the conditions which prevailed during the charcoal period.

The statistics of iron production during the early years of the industry were not collected, and the total amount of iron ore consumed can not be determined. Not until 1889 were annual statistics of ore production collected, though they are available for the two preceding census years 1870 and 1880, and the annual production of intermediate years may be derived from the known production of pig iron as far back as 1870. Basing an estimate upon the average pig iron production shown for census years prior to 1870, the total iron ore produced from 1810 to 1869 was approximately 49,656,000 tons, and on the annual production of pig iron from 1870 to 1888 it was 153,758,000 tons. These amounts added to the 475,162,000 tons produced from 1889 to 1907 give a grand total of 678,576,000 tons produced since 1810. The amount produced during the Colonial and Revolutionary periods and up to the third census in 1810 is so small in comparison with the total production since that time as to be a negligible quantity.

In deducing the iron ore production from the production of pig iron, it should be borne in mind that a small proportion of this iron was made from imported ores and also that some pig iron is made from other materials than natural ores, as blue billy, zinc residues, rolling-mill cinder, scrap, etc. On the other hand, iron ore is used for other purposes, as in the manufacture of paint, as a fix or fettling in puddling furnaces, and as a flux in silver smelting, and the amount so used practically offsets the amount of material other than iron ore charged into the blast furnaces.

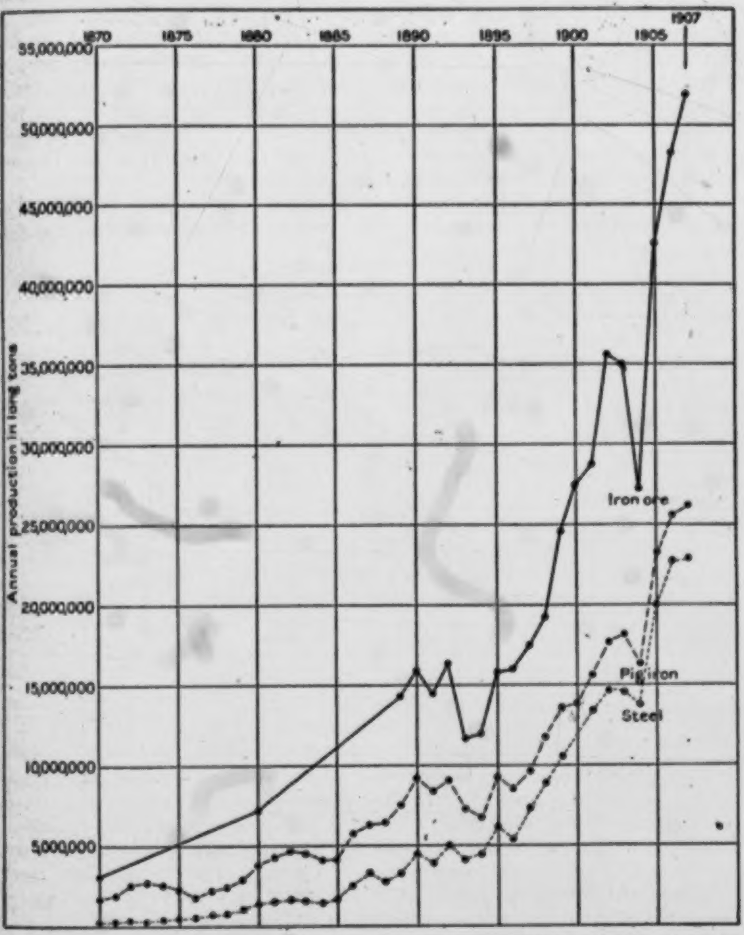

FIG. 1.—Curve showing the production of iron ore, pig iron, and steel in the United States, 1870–1907, in long tons.

The production of iron ore from 1870 to 1907, inclusive, is shown on the accompanying diagram along with the production of pig iron and steel for the same period.

The curve representing the production of pig iron shows more fluctuations than the ore curve, and that representing production of steel more than the pig-iron curve. In other words, the production of steel responds most promptly to varying industrial conditions. Thus the production of steel in 1907 shows practically no increase over 1906, while the rate of increase in ore is above the average for the preceding eighteen years. This is explained by the fact that the industrial depression of 1907 came so late in the year that it only slightly affected the output of iron ore, particularly in the Lake Superior district, where mining is more active in summer than in winter. It is practically certain, however, that the output of ore for 1908 will show a decided decrease similar to, and probably larger, than that which marked the years 1893–94 and 1904. The years 1892, 1902, and 1907 occupy maximum points in the curve, and each is followed by a decided drop and rapid recovery far beyond the preceding maximum. It may be safely predicted that the curve will resume its upward trend in 1909 after the drop of 1908.

The distribution of the production since 1889 among the varieties of ore enumerated in the chemical classification is shown in the following table:

Production of iron ores in the United States, by varieties, 1889–1907.

Year.	Magnetite.	Hematite.	Brown ore.	Carbonate.	Total.
	Long tons.	*Long tons.*	*Long tons.*	*Long tons.*	*Long tons.*
1889	2,506,415	9,056,288	2,523,087	432,251	14,518,041
1890	2,570,838	10,527,650	2,559,938	377,617	16,036,043
1891	2,317,108	9,327,398	2,757,564	189,108	14,591,178
1892	1,971,965	11,646,619	2,485,101	192,981	16,296,666
1893	1,330,886	8,272,637	1,849,272	134,834	11,587,629
1894	972,219	9,347,434	1,472,748	87,278	11,879,679
1895	1,268,222	12,513,995	2,102,358	73,039	15,957,614
1896	1,211,526	12,576,288	2,126,212	91,423	16,005,449
1897	1,059,479	14,413,318	1,961,954	83,295	17,518,046
1898	1,237,978	16,150,684	1,989,681	55,373	19,433,716
1899	1,727,430	20,004,399	2,869,785	81,559	24,683,173
1900	1,537,551	22,708,274	3,231,089	76,247	27,553,161
1901	1,813,076	24,006,025	3,016,715	51,663	28,887,479
1902	1,688,860	30,532,149	3,305,484	27,642	35,554,135
1903	1,575,422	30,328,654	3,080,399	34,833	35,019,308
1904	1,638,846	23,839,477	2,146,795	19,212	27,644,330
1905	2,390,417	37,567,055	2,546,662	21,999	42,526,133
1906	2,409,294	42,481,375	2,781,063	17,990	47,749,728
1907	2,679,067	46,060,486	2,957,477	23,589	51,720,619
Total	33,966,509	391,300,205	47,763,384	2,071,939	475,102,127
Percentage of totals for nineteen years	7.1	82.4	10.1	0.4	....
Percentage of total for 1907	5.2	89.1	5.7	....	....

The present relative importance of the several varieties is shown by the percentage and also the increasing importance of the hematite as compared with the other varieties. The combined total productions of brown ore and carbonate for the nineteen years is 2,000,000 tons less than the total production of all varieties for the year 1907.

The distribution of production for 1906 and 1907 among the six commercial districts is shown in the following table:

Production of iron ores in the United States, by commercial districts, in 1906 and 1907.

District.	1906.		1907.	
	Quantity.	Percentage of total.	Quantity.	Percentage of total.
	Long tons.		*Long tons.*	
1. Northeastern	2,582,666	5.40	2,822,822	5.45
2. Southeastern	6,208,140	13.00	6,197,360	12.00
3. Lake Superior	38,035,084	79.66	41,638,744	80.50
4. Mississippi Valley	117,570	.25	230,435	.45
5. Rocky Mountain	806,268	1.70	831,258	1.60
6. Pacific slope	(a)	....	(a)	....
Total	47,740,728	100.00	51,720,619	100.00

[a] The small production of California and Washington is included in the production of the Rocky Mountain district.

These figures indicate the commanding position of the Lake Superior district in the iron industry with 79.66 and 80.60 per cent of the total production for the two years.

DURATION OF THE IRON-ORE SUPPLY.

Predictions of the date of exhaustion of the iron-ore reserves involve a number of unknown factors, each of which adds to the uncertainty of the result. Among these factors the following may be mentioned:

1. The uncertainties of the estimates of reserves and the difficulty of fixing the ratio of the two classes have been fully explained in the sections devoted to the description of the ore deposits.

2. The extent to which imported ores will supplement the domestic supply can not be foretold, but it will be an increasingly important factor.

3. The extent to which the reserves will be increased by the discovery of new ore bodies can not be estimated, but it is highly improbable that all the important iron-ore deposits are now known.

4. The ores of the first class will not be entirely exhausted before utilization of the second class begins, and changing conditions, particularly of transportation and metallurgy, will continually shift the line dividing the two classes.

5. The stock of metal which can be reworked is constantly increasing and must eventually reduce the demand for metal obtained directly from the ores.

6. The substitution of other materials for metal now used for certain purposes, particularly for construction, will reduce the consumption to an extent which can not be even approximately estimated, and, on the other hand, the proportion of structures into which iron enters as an important constituent will undoubtedly increase.

7. The per capita consumption of iron ore has shown a rapid increase since the beginning of the iron industry. For 1907 and the four preceding census years it has been as follows: 1870, 180 pounds; 1880, 313 pounds; 1890, 560 pounds; 1900, 806 pounds; and 1907, 1,344 pounds.

8. The increasing cost of iron due to the increase in cost of fuel and the use of lower-grade ores requiring an increased amount of fuel per ton of iron smelted, will induce greater economy in the use of the metal; on the other hand, improvements in metallurgy will tend to secure a larger yield of metal for a given expenditure of fuel and power and may substitute low-grade fuel for the higher-grade coal now required in the blast furnace.

The most striking feature of the iron-ore production curve is the remarkable rate of increase shown in the period covered. Taking the production since 1870 by decades and estimating the last two years of the present decade, 1908 and 1909, the percentage rate of increase for each decade over the one preceding is shown in the following table:

Production of iron ore by decades and rate of increase.

Decade.	Quantity.	Percentage of increase.
	Long tons.	
1870-1879	43,770,527	....
1880-1889	91,043,854	108.0
1890-1899	163,989,193	80.1
1900-1909	[a] 392,000,000	138.0

[a] Approximate.

Each of the above decades, as shown by the production curve, contains a depression in which there was an actual decrease in production, so that they may be taken as fairly representing the tendency of the industry. These rates of increase are such that they do not permit the construction of a curve on which predictions for the future can be based. A comparison of the first and second rates, 108 and 80.1, would indicate a rapid decrease in the rate of increase, which, if continued, would have placed the date of maximum production about 1930. But a comparison of the second and third rates, 80.1 and 138, would indicate a rapid increase in the rate of increase. If the average rate of increase by decades, 108.7 per cent, should be continued, it would require the production in the next three decades of 6,088,000,000 tons. But the ore supply now available in the United States is estimated at 4,788,000,000 tons, which is only 78 per cent of the amount needed on this assumption. It is evident, therefore, that the present average rate of increase in production of high-grade ores can not continue even for the next thirty years, and that before 1940 the production must already have reached a maximum and begun to decline, and a very large use must be made of low-grade ores not now classed as available. The second condition, with its consequent greatly increased cost of iron, is the only thing which can prevent a decline in the iron industry, measured by the amount of pig iron produced, within the next thirty years, unless there is in the meantime very greatly increased importation of foreign ores.

In view of the many factors entering into the problem, the tendency of which is not always determinable, to say nothing of the weight that should be given them, any further prediction as to the date of exhaustion of the iron-ore supplies is so uncertain as to be wholly unprofitable and unwarranted.

RESOURCES OF THE UNITED STATES IN GOLD, SILVER, COPPER, LEAD, AND ZINC.

By W. Lindgren,
United States Geological Survey.

INTRODUCTION.

The ores of gold, silver, copper, lead, and zinc occur as a rule in localized deposits of varying form, depth, tenor, and geologic relations. There are no wide areas underlain by strata of ore with maintained characteristics. The ore deposits are exceptional occurrences. They are concentrated, it is true, in a number of localities, but the bodies are ordinarily of very irregular form, and it is difficult to predict what each new level in a shaft, each new drift on a level, will disclose. Some of the large companies mining copper, lead, or zinc ores have extensive reserves blocked out by actual development work or by borings, but the ore developed is rarely sufficient for more than a few years' work. The majority of the companies would undoubtedly decline to furnish detailed information on this subject.

The distribution of values is even more capricious in precious-metal mines than in base-metal mines, and in the case of gold the number of companies operating lode mines with large reserves can be counted on the fingers. Concerning deposits of gold-bearing gravels or placers, a somewhat more accurate statement can be made as to the probable extent of resources. These remarks serve to make clear the impossibility of ascertaining even the approximate extent of the total supply of metallic ores. The best that can be done is to forecast in a rough way the probabilities of the immediate future on the basis of the experience of the past. In doing so, it is well to bear in mind that many of the predictions ventured on this subject during the last fifty years by able men have proved very wide of the mark.

The conclusions reached in this report are based chiefly on investigations by the geologists of the United States Geological Survey.

MINERAL LANDS OF THE UNITED STATES.

The mineral-bearing lands still owned by the United States are largely confined to the Cordilleran States. The mineral lands of the Southern Appalachian States are privately owned, and as far as the total production is concerned they cut a small figure. Likewise, the copper-bearing lands of Michigan and the lead-zinc lands of Missouri and other States of the central valley have passed into private hands. There remain the States of Colorado, Wyoming, Montana, Idaho, Utah, Nevada, Washington, Oregon, and California, as well as the Territories of Alaska, Arizona, and New Mexico, in which there still exists a large aggregate area of mineral land belonging to the United States. The extent of the mineral land of the United States still owned by the Federal Government is an unknown quantity because (1) the mineral lands have never been segregated and surveyed, and (2) a very large acreage is simply held by assessment work, and the present laws do not require that such claims shall be surveyed or registered. It is true that the majority of claims on which valuable mines have been developed have passed to patent. But there are thousands, in fact, hundreds of thousands of claims on which mineral has been discovered, which are held by annual assessment work, and of which the General Land Office has no record whatever. Even many important producing mines, and practically all placer mines of Alaska, are thus held. This condition is made much worse by the fact that according to present laws anyone—individual or company—can locate an unlimited number of claims provided the assessment work is performed. As no assessment work is required until a year to two years after discovery, this rule works out so that a newly discovered camp is completely covered by locations by the first comers, and its growth may be seriously interfered with. In case of specially valuable discoveries the early arrivals are thus granted an unreasonable privilege which is always abused. The process is well known throughout the West, and is popularly known as "claim hogging."

The first steps toward ascertaining the area of mineral land still belonging to the United States would seem to be: (1) Survey and segregation of mineral lands; (2) registration of all mineral claims at the land office of the district.

Any estimates on the basis of available data are useless.

The first requirement, segregation of mineral lands, is no doubt easier to demand than to execute. There is no possibility, as with coal deposits, to segregate large areas with the confident knowledge that the mineral exists below them. For instance, a mountain range may present a favorable aspect from a geologic standpoint for the occurrence of metals, and yet no deposits may be found in it except perhaps within one limited area. However, the possibility always remains that some careful and deeper prospecting may reveal ores in the part hitherto considered barren.

A worse complication is involved when the land is valuable for several purposes. It may be good agricultural land; even if situated in the mountain regions it may, as is frequently the case in California, be valuable for horticulture and viticulture, or for pasture. Here is a conflict between permanent and temporary value. The land will always produce fruits, but the gold deposit below it will, in all probability, be exhausted in a limited time, very soon, indeed, in the case of many buried gravel channels. Such conflicts have caused much loss and annoyance in California. How can these two values be compared and measured?

A difficulty even more troublesome arises when the land is valuable for both its mineral and its forest. Here, however, we have to measure two more commensurate values, both of more temporary character than in case of agricultural lands. The value of the forest can usually be measured with some accuracy. The value of the mineral on the same land can usually not be measured with exactness. Very often the former will exceed the latter, as far as surface developments go, and then the question arises whether it is justifiable to interfere with free prospecting and search for metals in order to more effectively preserve the forests.

It would seem that the present interminable conflicts could be avoided only by a separation of the mineral and forest rights, while retaining for agricultural patents the right to possible later discoveries underneath the ground. The forest lands have great value, and as long as human nature remains what it is even the bona fide miner will continually attempt to gain possession of them by unduly extending his mineral locations. Many mining districts are covered with a scant growth of forest, barely enough for the miner's needs for timber and fuel. Such lands should not be classified as forests.

WASTE.

The prevention of waste in mining and reduction processes is a most important subject. Whatever our views of future necessities, it is clearly not right to carelessly waste the metallic treasures of the earth, and in this direction much can be accomplished. The loss is rather in processes of concentration and reduction than in mining. In some cases pillars of ore are left, but the shape of the deposits is generally such that all the ore can be extracted without much loss. In industries like copper mining, where the term "ore" has rapidly changed its meaning within the last decade—where, in other words, ore containing 1, 2, or 3 per cent of copper can now be mined profitably where it was formerly considered waste—it is clear that large bodies must be left now which later may possibly be extracted with profit. But this ore is, of course, not lost unless the whole mine goes to wreck.

In concentrating and milling the greatest losses occur and the percentage of these is largest in the low-grade deposits. In the earlier days of gold and silver milling enormous amounts of rich tailings were sent down the creeks and gulches and permanently lost, largely because of conviction that the values could not be recovered, partly perhaps because of disinclination to let it be known that the tailings contained any values. Matters have changed in this respect, and tailings are now generally stored with a view to possible reworking. No doubt the States could aid this practice of economy by legal requirement of such storage, a policy which besides is desirable in order to avoid contamination of the water supply.

The losses of gold, silver, copper, and lead in smelting are generally not large, and, moreover, the slag is necessarily and easily stored. In many cases the slags of earlier years have been worked over. By far the greatest losses take place in the concentration of copper, lead, and zinc ores. They probably reach their maximum in zinc ores or in copper ores with soft metallic minerals like chalcocite, and here often attain 30 per cent or even 40 per cent. These operations are also conducted on a large scale, making storage of tailings difficult, but the same principle should be applied by legal requirements wherever possible. Somewhat better conditions now prevail in Missouri than formerly, but some years ago it was not at all uncommon to have losses in zinc concentration reaching 40 per cent.

No doubt it will be impracticable, under our system of government, to compel mine owners to prevent unnecessary waste by prescribing certain working methods. Probably no European state has ever gone so far. Storage of tailings will probably prove to be the best remedy if it can be legally enforced.

It is perhaps in the utilization of by-products that we have most to learn, but the standpoint is naturally taken by miners and smelting men that if it can not be done with profit it had better not be done at all. I refer specially to the smelter fumes and to the extremely large quantities of sulphur and arsenic that are driven off in the air, sometimes with great damage to the surrounding agricultural districts. The case of arsenic is especially interesting. The statement is made by F. L. Hess[a] that—

> Enormous quantities of arsenic in fumes continually escape from the smelters of the country, while at present comparatively little arsenic is saved. Harkins and Swain (Jour. Am. Chem. Soc., vol. 19, 1907, pp. 970–998) state that in August, 1905 (when the experiments were made), from the Washoe smelter, which works exclusively upon Butte copper ores, 59,270 pounds of arsenic trioxide per day were passing through the stack. This is equivalent to 10,817 short tons per year, and is exclusive of what arsenic trioxide was saved from the flues. At 5 cents per pound, the lowest price for which white arsenic sold in 1907, this waste product of one year would be valued at $1,081,700. The waste arsenical fumes at this plant alone amount to more than six times the domestic saving of arsenic trioxide, and to much more than the combined production and imports of arsenic in the United States each year.
>
> At the Butte reduction works and the Great Falls smelter other great quantities of more or less arsenical Butte copper ores are treated, from which no saving of arsenic is known to have been made, and from which the losses must be very great.
>
> In Utah both the Bingham and the Tintic copper ores are arsenical, and no saving has yet been made from them, though immense quantities of ore are smelted.
>
> It is recognized that in handling a low-priced product like arsenic, saving can not be carried to extreme refinement without becoming unprofitable. However, arsenic is now being extracted from sulphuric acid at a number of establishments in England, and both products are cheap articles. If even one-half of the arsenic wasted were saved, the market in this country would be glutted. However, without taking account of the possibility of greater demand, if there were a greater supply at a somewhat lower price, there will in time probably be some plan devised for the better saving of smelter fumes, through the operation of which it will be unnecessary for this country to import arsenic while so much is continually being wasted.

Smelter fumes occupy a similar position to tailings in mills, but they can not, of course, be stored. On the contrary, they spread over the country, frequently damaging the vegetation near the smelter, and the compulsory saving of the sulphur and arsenic contained will probably soon, in most cases, be required by law.

In many cases the waste in mining and milling is the result of ignorance. Dissemination of knowledge and investigation of methods by bureaus of the Federal Government and the States will do much to check the waste.

GENERAL CONCLUSIONS.

The individual reports on the separate metals will show that the resources in each case are very large, but that they can not (with few exceptions) be measured with any accuracy. To give definite figures representing our metal supply is quite out of the question. It will be shown that our resources of silver, copper, and zinc are very large and that a moderate rate of increase in production can be maintained probably for the next twenty years at least. In case of lead it is not probable that the production can be very greatly increased. While it is true that, with a continuation of the present increasing rate of production, the known reserves, workable under present conditions, will be exhausted before the middle of the present century, this prediction should not be announced without important qualifying clauses. The nature of the case prevents a full knowledge of our resources. They are developed by mining operations only, and exploration does not materially anticipate unusual demand. Ten years ago a review of our metallic wealth would have revealed a far greater shortage in the supply of metals than is now believed to exist, and it is probable that, in case of some metals at least, ten years from now our resources will be known to be greater than they are at present. The higher grade of ores of copper and lead are growing scarce, but improvements in technologic processes, by lowering the cost of reduction, have added great quantities of lower-grade material to our available ore supply, and will probably continue to do so. With increasing demands quantities of old metals will be returned to use. The importance of this factor is great, but it is difficult to measure. In case of gold it does not seem likely that, on the basis of present developments and processes, our production can be made to greatly exceed $110,000,000 per annum for the next twenty years. And on the same basis it would seem likely that after some such period the gold production would gradually decrease.

---

[a] Mineral Resources, U. S., for 1907, separate on "Antimony and arsenic," p. 9.

If we were sure that the development of the world would proceed indefinitely on the same lines as those of to-day; that metals would have the same value; that the same metals would be used for the same purposes; then it might be possible (to use an expression of Professor De Launay[a]) "to strike a balance between us and our descendants." We have not this knowledge. We may forecast what is likely to happen and what our needs will be in the metal industry, for the next ten, twenty, possibly fifty years. The conditions and developments in the more distant future are completely beyond us.

It is reasonably certain that the industrial development of the world will continue on an ever increasing scale. But who can tell us what methods and materials will be used, and what new discoveries in little explored continents will disclose? Substances now eagerly sought may then be of little value; reserves established by the States may be useless and simply serve to restrict the present development. Legislative interference with production of metals is likely to be futile and probably can not in the long run successfully interfere with the operation of economic principles based on laws of supply and demand.

GOLD.

PRODUCTION OF THE UNITED STATES.

Since 1892 the gold production of the United States has increased at a very rapid rate. An output of $60,000,000 was recorded in 1852 and 1854, shortly after the discovery of the California placers. From that time the production decreased gradually to $30,000,000 in 1883 and 1884 and then rose slightly, remaining at about $33,000,000 from 1885 to 1892. The effect of the Cripple Creek discoveries and of the application of the cyanide process became apparent after 1892 and the production steadily mounted to about $80,000,000 in 1902. A serious falling off in Colorado reduced the total in 1903 to $73,500,000, but during the next four years in consequence of the discoveries in Alaska and the development of the dredging industry in California, there was a renewed rise which culminated in a production of over $94,000,000 in 1906.

---

[a] De Launay, L., La conquête minérale, Paris, 1908, p. 379 et seq.

In 1907 the output fell to $90,400,000, but a further decline is not probable for 1908. The causes of the decrease in 1907 were the generally disturbed financial conditions, labor troubles, and a scarcity of water in Alaska.

The output of the United States is shown in the accompanying diagram.

PRODUCTION OF THE WORLD.

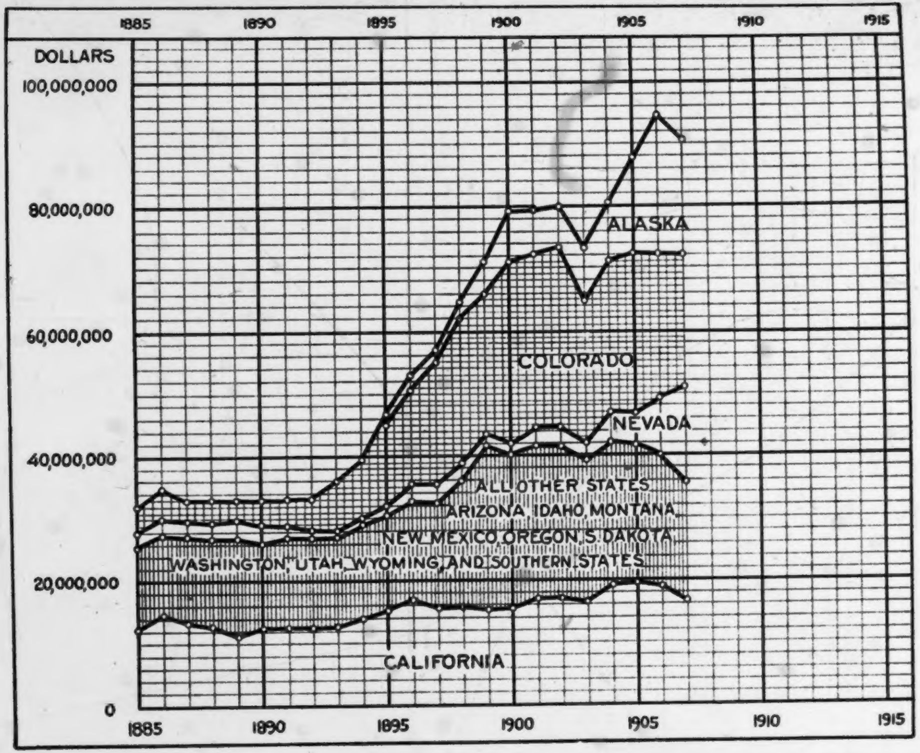
The rapid increase in the annual production of gold of the world is a feature which has been the subject of much discussion in its relation to the monetary systems and financial affairs generally. The facts are best brought out in the accompanying diagram. California and Australia in the early fifties brought the production rapidly to $180,000,000 from about $10,000,000 in 1830. The output in the earlier part of the century was largely derived from Russia. The gradual decay of placer mining in California and Australia reduced the yield for the world to nearly $100,000,000 about 1886. In the period from 1885 to 1890 numerous discoveries in South Africa, in Western Australia, and in Colorado changed the aspect of the industry.

The cyanide process, which gave better extraction at reduced cost, was introduced about this time. In South Africa especially this process has proved of the utmost importance. A little later discoveries were made in Alaska, Nevada, the Canadian Yukon, Mexico, Rhodesia, and West Africa, notwithstanding the assertion made by many that no further important supplies of gold were likely to be found.

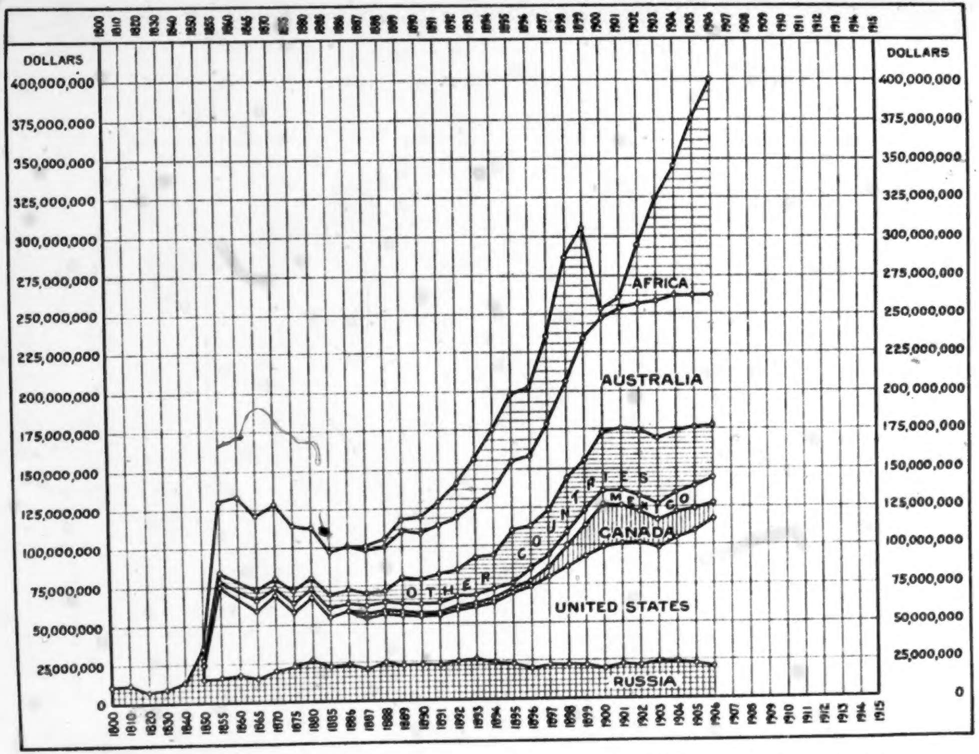
Thus, since 1887 the production of the world has been trending upward, except for the temporary decline due to the Boer war, and in 1907 was about $412,000,000. It will be observed that Africa now (1907) contributes about $151,000,000, or one-third of the world's production, and of the African output about $133,000,000 comes from a small district in the Transvaal.

Barring new and unexpected discoveries it is believed that the world's production will not increase hereafter at the recent rapid rate of advance. It is believed that the maximum production has nearly been reached in the Transvaal, although the present output can be maintained for a long time, probably for more than thirty years. The output of Australia from present indications is more apt to decline than to increase.

As indicated by the diagram, the production of Russia forms a solid and constant substratum on the permanence of which it is fair to rely. A continued increase in the United States is scarcely to be expected, although the recent history of gold mining in Nevada



THE PRODUCTION OF GOLD OF THE UNITED STATES AND OF THE PRINCIPAL STATES AND TERRITORIES FROM 1885 TO 1907.



THE PRODUCTION OF GOLD OF THE WORLD AND OF THE PRINCIPAL COUNTRIES FROM 1800 TO 1906.

(After E. Biedermann.)

shows what unsuspected riches may lie for decades within easy reach. It is true that there are large unprospected territories in South America which with developing lines of communication may produce much gold, but on the whole the probabilities of the immediate future are rather in favor of maintenance of the present level of output than of a further sensational advance.

RESOURCES OF THE UNITED STATES.

The diagram shows that the production of the United States can, for present purposes, be divided into five parts. In 1907 Colorado, Alaska, California, and Nevada in the rank indicated contributed each from $15,000,000 to $20,000,000 to the total output. The remaining fifth part, approximately $19,000,000, came from Utah, South Dakota, Montana, Arizona, Idaho, and Oregon, the amount from the remaining States (southern Appalachian region, New Mexico, Washington, and Wyoming) being negligible.

IDAHO AND OREGON.

Great constancy has been shown by Idaho and Oregon in their gold output, which for each State generally is below $2,000,000 per annum and may be expected to continue on the same basis for many years to come. The product is from placers and gold-quartz veins.

SOUTH DAKOTA.

In South Dakota the output has varied since 1889 from $3,000,000 to $7,000,000. Of this about $5,000,000 is derived from the Homestake mine, the most productive gold mine in the United States. The total yield of this mine approaches $60,000,000. A large tonnage of low-grade ore (about 1,400,000 tons per annum) is treated in a mill with 1,000 stamps. The deposit, as far as known, does not approach exhaustion; the shafts have not attained great depth. The blanket deposits in limestone may be exhausted at an earlier date than the Homestake, though the reserves appear to be fairly large. It is likely that South Dakota will be able to maintain its production for a long time.

ARIZONA.

Arizona has for many years supplied from $1,000,000 to $3,000,000, which is derived about equally from the copper ores of United Verde, Globe, and Bisbee on one hand, and the gold-quartz mines of Yavapai, Mohave, and Yuma counties on the other hand. From neither source is much falling off to be expected for the next ten years; a moderate increase is more probable.

MONTANA.

Montana has long maintained a steady gold production ranging from $3,000,000 to $4,000,000. For some years $1,000,000 has been derived from the Butte copper ores, and an equal amount from cyaniding the quartzose ores of Fergus County. The latter supply, however, has recently shown a sharp decline. The balance of the

State total has come from a great number of small gold and silver mines in several counties. It is not likely that the production of Montana in the near future will sink below $3,000,000.

CALIFORNIA.

The California production is notable for its constancy. Since 1885 the State has annually supplied from $12,000,000 to $19,000,000 in gold. The rise noted in the diagram during the last few years is largely due to the development of the dredging industry. In 1907 the State produced $16,900,000, which, disregarding some minor sources, may be divided as follows: Quartz mines, $9,400,000; copper mines, $350,000; placer mines, $6,800,000. The production from quartz mines has of late decreased, but it may be relied upon to continue, with fluctuations, for a long period. There are few very large mines, but there are many which have shown ability to maintain moderate production for many years past. Few of the mines have ore developed for more than two or three years, and even approximate figures as to future reserves are out of the question. On the other hand, a long-continued and steady output gives assurance of a continuance for a long period of years, with probable ultimate diminution. The gold from copper ores will increase, and may in a few years reach $1,000,000.

The placer-mining industry of California presents some interesting features. For many years the production from this source gradually decreased. This was largely due to the prohibition of hydraulic mining in the drainage areas of Feather, Bear, Yuba, and American rivers on account of the damage done to farming lands and to the harbor of San Francisco.

In the last ten years gold dredging has been developed to a high degree in consequence of the improvements in dredge construction and of the discovery that a large area near the mouths of the rivers flowing from the gold-bearing region of the Sierra Nevada is available for such mining. The output from the dredges in 1907 was somewhat over $5,000,000. Very sanguine predictions have been made as to the amount of land available for dredging in California and in the Rocky Mountain States, and to some degree they are justified. The fact remains, however, that the production of the Rocky Mountain States from dredging is as yet very small (about $300,000 in 1907), and it is believed that there are no extensive areas which at all compare with those at the base of the Sierra Nevada. It is estimated by the most competent authorities that the known dredging lands in the great valley of California amount to 18,000 acres. If an average depth of 45 feet, corresponding to 72,600 cubic yards of gravel per acre, and an average content of 12 cents per cubic yard, or $8,712 per acre, be assumed, then 18,000 acres would ultimately yield $156,800,000. Up to 1905 about 700 acres had been worked. This crude estimate may be considerably off the mark, but it serves to show that a large amount of gold is contained in the dredging lands, and that the industry will be of great importance for the next quarter century at least. The total dredge production of California since 1900 is about $18,000,000.

It has been stated that the production of the placer mines, outside of the dredges, has receded pretty steadily for many years, and that this is due to the practical prohibition of hydraulic mining in the basins of the principal rivers draining into the great valley. The gold reserves in these gravels are undoubtedly very large. Were these mines allowed to operate, several million dollars per annum could undoubtedly be added to the California production. Estimates by the United States engineer officers indicate that in the basins of the Yuba, American, and Bear rivers 1,500,000,000 cubic yards of gold-bearing gravel would ultimately be available by expensive development work, consisting in tunnels, ditches, etc., the amount at present available being about 500,000,000 yards. Adding to this estimate 100,000,000 cubic yards for the Feather River and the southern rivers draining into the San Joaquin, we would have 1,600,000,000 cubic yards, much of which is poor, but which may be assumed to average 6 cents per cubic yard.

According to this rough estimate nearly $100,000,000 in gold would be available if the hydraulic mines of the central gold region were permitted to work. Siskiyou and Trinity counties now yield $600,000 per annum from their hydraulic mines. The extent of the reserves in these counties is less well known, but they are believed to be large.

No State or Territory (except Alaska) compares with California as to the probable extent of gold reserves. There is reason to believe that California can maintain a production of $15,000,000 per annum for the next fifty years, and that then it probably would not be exhausted. Ultimately, of course, the gold reserves would become smaller, as has been the experience of the European countries in which gold mining once flourished. Eventually the gravels will be worked out, the dredging ground exhausted, the quartz mines impoverished or difficult to work on account of increased expense at depth. But this is looking far into the future. What the accompanying industrial conditions will then be is beyond our ken.

ALASKA.[a]

Though recently discovered, the mineral resources of Alaska have proved to be enormous. The total production of gold has risen rapidly and almost continuously since 1890. It reached $21,400,000 in 1906, but fell to $18,500,000 in 1907, and may decline somewhat further in 1908. This recession is, however, only temporary, for it is believed that the resources in placer gold are very large. The total gold output of Alaska since 1880 is about $122,000,000. Of this about $25,000,000 was produced from quartz mines in southeastern Alaska, which annually yield about $3,000,000. The Treadwell Island group of mines is the principal factor, with an ore production of 1,400,000 tons per annun and a recovery of about $2.50 per ton. The deposit can be compared only to that of the Homestake mine in South Dakota, and, so far as known, the ore body shows no contraction or serious diminution of tenor in depth. The greatest depth now attained is 1,650 feet. Probably no obstacles to mining at far greater depths will be encountered, and the present production seems assured for many years. There are other important quartz mines in process of development.

---

[a] A more detailed report on the Territory will be contributed by Mr. A. H. Brooks, of the Alaska division of the U. S. Geological Survey.

The placer fields of Alaska are chiefly in the Yukon basin and in Seward Peninsula. Mr. A. H. Brooks has shown that in the latter region the gravels contain a total of about $300,000,000. There is probably as much in the Tanana (Fairbanks) and Yukon basins and the largest part of this will probably be extracted by dredging. With better communications and with the development of technical methods, gravels of lower grade can be worked, although the lowest grade of material possible to handle must remain very much higher than for corresponding gravels in California. While in the latter State 10 cents per cubic yard will yield a profit, 50 cents will probably be the lowest limit for some time to come in Alaska, where steam thawing must be resorted to as a rule.

The copper deposits will add a certain, though not very large, amount to the gold production and it is not impossible that workable gold-quartz mines will be discovered in Seward Peninsula and on the Yukon.

As far as visible supplies are concerned Alaska stands easily first in the United States and will yield a large annual production of gold for a long period of years.

COLORADO.

Until 1892 Colorado was of comparatively small importance as a gold producer. From three to four million dollars were contributed with great regularity from the Gilpin-Clear Creek field and the San Juan region. The former field continues its production steadily with few changes; the depth attained is comparatively small and a continued yield of about $2,000,000 may be expected for an indefinite time. The San Juan region came into prominence some fifteen years ago with the development of the Telluride, Ouray, and Silverton mines and now yields annually $5,000,000 to $6,000,000. Some mines bid fair to continue for many years; others show signs of exhaustion, but the region has great possibilities and a long-continued production may be expected. In most cases reserves of "developed" or "probable" ore are not large. One prominent gold mine in this region now has reserves for two years in sight; but few have more and many have less.

The unexpected discovery and development of the Cripple Creek district in 1890 brought Colorado to the front as a gold-producing State and rapidly increased the State's output from an average of $4,000,000 to nearly $29,000,000 in 1900. In 1907 the gold production of Colorado was about $21,000,000. The new district proved extremely rich, but the largest ore bodies have now been worked out down to the depth of the lowest drainage tunnel. The quantity of ore above that tunnel has been enormous. Including 1907, Cripple Creek has produced $179,000,000. The maximum production of $18,000,000 was reached in 1900. In 1907 the output was $11,000,000. The future of Cripple Creek is largely dependent upon the character of the veins below the present tunnel level. A new tunnel 700 feet below the present drainage level is now being driven, but it will be at least two years before it will have reached the producing area. It is believed that the deposits will be less rich at greater depths, but the tunnel is likely to open many important ore bodies and its completion should be followed by an increase in the output, which may be maintained for many years. But it should be steadily borne in mind that this is only a probability. We know little about the conditions or the size of the ore shoots below the bottoms of the present shafts.

The conditions in Colorado are very different from those in California and Alaska. There are few extensive gravel beds which may be confidently predicted to yield millions of dollars. Basing an opinion as to the output of the future simply on the records of the past, one may say that the State will probably be able to maintain a production of $15,000,000 to $18,000,000 for a long period, and that the ultimate exhaustion of its lode mines is probably far distant.

NEVADA.

The gold-mining industry of Nevada has been characterized by sudden outbursts of high production followed by periods of depression. The bonanzas of gold and silver ores of the Comstock, Eureka, Tuscarora, and Pioche in the seventies were rapidly exhausted; then followed two decades from 1883 to 1903 of small gold production ranging from $1,000,000 up toward $4,000,000. The discovery of Tonopah and Goldfield brought another sudden rise in production, and in 1907 it attained $15,000,000, of which $11,000,000 was derived from the two new gold camps. The State has been very extensively prospected during the last eight years, and many new camps have been discovered, which, with improvement of methods and communications, will add their quota to its output.

To this State applies in a still higher degree what has been said about Colorado. The known reserves of ore are generally small, while their grade is high. One important mining corporation states in its report that it has reserves of about $8,000,000 in value, but this is exceptional. Other mines now producing will probably be exhausted in a short time. On the whole, however, it is likely that the aggregate output from the many mining camps already discovered will be sufficient to keep the production of the next ten years at least close to the $10,000,000 mark.

The copper mines of Ely will soon afford a steady yield of $300,000 to $500,000 per annum in gold as a by-product. Discoveries of deposits of great importance are always possible in Nevada.

CONCLUSIONS.

In the preceding paragraphs it has been shown that the reserves in gold of the United States are great, but that they can not be appraised with anything approaching exactness. Only in case of the placers is a rough estimate possible. It has been shown that the resources in placer gold are chiefly in Alaska and California. Based on present methods of working and present wages the recoverable amount of gold in these placers would perhaps approximate $1,000,000,000. The other States have also resources in placer gold, but they are of importance only in Montana, Idaho, and Oregon, and even in these States they are small compared to Alaska and California.

The placer gold won in the United States in 1907 amounted to about $24,000,000, and it is believed that this quantity can be supplied for a long succession of years. Ultimately the placers will be exhausted.

The amount of gold derived from copper ores in 1907 was only about $5,500,000, but this represents a stable and even increasing quantity which is to be relied upon at least for the next quarter century and most likely much longer. The gold derived from lead ores is much less (only about $2,100,000), and will probably slowly decrease for the next ten or twenty years.

From quartzose gold and silver ores $55,000,000 was recovered in 1907. No calculation can be made as to total reserves available, and the figures, could they be collected, would be of little use. Mines will be exhausted, but new ones are coming in. Ore shoots are worked out, but others are found. Most of the mining districts have as yet attained only a very moderate depth, and it may be said that the resources of siliceous gold ores are very far from being exhausted. Just how long they will last nobody can tell. In a general way ore deposits are more likely to decrease than increase in richness as depth is attained, and at the same time the operating costs are likely to become higher. It would seem that this ultimate decline is rather far off at the present time. Certain parts of the western country, particularly Nevada, Washington, and Idaho, still suffer from inadequate railroad communication, and each new line as a rule leads to the opening of a number of deposits which previously were unprofitable.

New discoveries are always possible and in some regions are probable. Methods of working are steadily improved.

Unless very important new discoveries are made it is thought unlikely that the production of gold in the United States will rise much above $110,000,000. Nor is it likely that it will sink below $60,000,000 within a long period of years.

The gold-bearing gravels and the dredging lands of California and other Cordilleran States have long ago passed into private hands. Only in Alaska are there any considerable amounts of such public lands left. It is believed that it would be in the highest degree inadvisable to withdraw from location any part of the placer lands of the public domain.

Regarding lode mines it must be remembered that land classed as mineral and part of the public domain may or may not be valuable. The value can, as a rule, be esablished only by expensive prospecting operations. To withdraw such mineral lands or to put a royalty on the product would be unwise.

WASTE.

There is comparatively little waste in the mining of gold ores. In the concentration of base ores the loss of gold is large, probably 30 per cent, but there is a relatively small amount of gold involved. In the usual combined process of amalgamation and concentration followed by cyaniding or in chlorination the loss is small; the recovery is generally about 90 per cent. In the recovery by smelting the loss of gold is extremely small and practically all of it is collected in lead or in copper matte. In electrolytic refining of copper and lead the loss is negligible.

At the same time it would be advisable to make storage of mill tailings compulsory. The reworking is sometimes profitable and can be done at little expense.

Much has been said about the loss in placer mining and in hasty operations in rich ground, as in Alaska; this is undoubtedly heavy, as attested by the repeated working of such ground. Even in better constructed plants there is some loss of fine gold, but the recovery is probably 95 per cent. In plants of the best kind, for instance hydraulic installations with undercurrents or dredges with the most improved appliances, the recovery may be considerably higher. It should be added, however, that few exact data concerning these losses are available.

CONSUMPTION.

The consumption of gold in the United States approximately equals the production; at least this appears to be true for the last thirty-five years.

In 1906, according to the Director of the Mint, the quantity of gold used in the arts, exclusive of gold coin and old material, had a value of about $29,000,000. (Total amount used in the arts, $39,000,000.) The quantity used has doubled since 1900. In 1906 gold was coined to the amount of about $79,000,000.[a] The total gold used for coinage and the arts in the United States in 1906 had thus a value of $108,000,000, or $14,000,000 more than the domestic product. The records show that a balance of $109,000,000 was imported during the same year, so that for 1906 $203,000,000 would represent the consumption of gold in the United States. The amount imported in 1907 was, however, unusually large.

For the period 1901–1905, according to Mr. Biedermann's[b] figures, the addition to the gold stock of the United States was $412,000,000, and this figure is $8,000,000 less than the domestic production for the five years. According to this the United States retained practically all of the gold produced within its territory for this time.

The total metallic stock of gold held in the United States on December 31, 1906, was, according to the estimate of the Director of the Mint, about $1,600,000,000. The production of the United States since 1873 is $1,650,000,000.

The total stock of gold coins in the world in 1905 was $8,050,000,000. Adding to this $2,000,000,000 as the probable amount used in the arts, we have a total of $10,000,000,000. Against this the total gold production of the world since 1860, according to the Director of the Mint, is $7,652,000,000.

The gold production of the world for the five-year period, 1901–1905, amounts to about $1,688,000,000.[c] This has ultimately been divided between the nations as follows: United States, $412,000,000; France, $378,000,000; Germany, $242,000,000; India, $177,000,000; Great Britain and Austria, each $112,000,000.

The flow of gold to India and Egypt has often been emphasized in the press. No doubt such importations are manufactured into jewelry or are hoarded and are permanently lost to commerce and industry. The above figures will show, however, that such hoarding has not caused the great demand for gold during recent years. The real cause is the heavy absorption of the metal by the commercial nations in order to fortify their monetary position. The introduction of the gold standard has forced those great nations to create large gold reserves. This process has been going on for the last twenty years, but from now on the demand for gold for this purpose will probably slacken.

---

[a] Probably $6,000,000 of this consisted of mutilated domestic coins and scrap.

SILVER.

PRODUCTION OF THE UNITED STATES.

The silver production of the United States became of importance about 1860 and increased rapidly up to 1892, when it attained 63,500,000 fine ounces. The decline in the price had begun in 1875, and in the year of maximum output the price had fallen to 88 cents per fine ounce. Since 1892 the yield of silver has remained practically constant, averaging about 55,000,000 ounces. In 1907 it was 56,500,000 ounces, but the present year will witness a considerable decline. The lowest price of silver was about 47 cents, in 1902. The price rose to 70 cents in 1907, but has again declined to 50 cents, in October, 1908. The general result has been that a great number of mines which extracted silver ores have closed down, but the compensating factor that an increasing quantity has been obtained as a by-product from lead and copper ores has kept the output steady. The lower line in the diagram shows the course of the production of the metal in the United States.

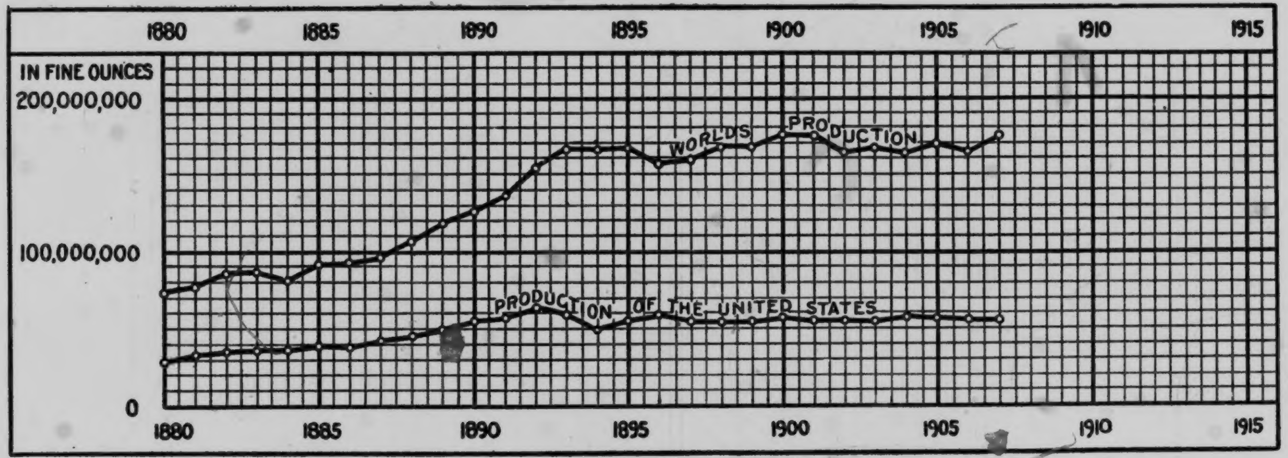
PRODUCTION OF THE WORLD.

The world's production of silver was 92,000,000 ounces in 1885, and about 178,000,000 ounces in 1907. The upper line in the diagram represents the world's production in the same time, and it well illustrates the constancy of the supply. The United States and Mexico are the most important contributors to the production of the world, the supply from each source being from 55,000,000 to 65,000,000 ounces. The rehabilitation of the mining industry of Mexico, which has taken place in the last twenty years, has gradually increased its output to more than double that of 1885. The remaining third of the world's production is mainly derived from New South Wales, Germany, Peru, and Bolivia. In many countries the output of silver is receding, owing to low price and difficulty of competing with the United States. To offset this, the silver output of Canada has lately been increasing at a rapid rate, and in 1907 attained nearly 20,000,000 ounces.

RESOURCES OF THE UNITED STATES.

The silver-producing States had in 1907 the following rank: Colorado, Montana, and Utah, each producing slightly over 11,000,000 fine ounces; Nevada and Idaho, each yielding about 8,000,000 ounces; Arizona, 3,000,000 ounces; and California, 1,500,000 ounces. None of the remaining States produced over 600,000 ounces.

An analysis of the statistics of 1906 is published in Bulletin 340 of the United States Geological Survey. From this it appears that the total output, disregarding the small amount of silver obtained from placer gold, was derived as follows: From lead, copper, and zinc ores, 40,100,000 fine ounces; from quartzose gold and silver ores,



THE PRODUCTION OF SILVER OF THE WORLD AND OF THE UNITED STATES FROM 1880 TO 1907 (IN FINE OUNCES).

16,500,000 ounces. A large proportion of the base-metal ores contained only a small amount of silver, which might be properly regarded as a by-product. Quartzose gold ores also contain silver which is recovered as a by-product and from this source 4,000,000 ounces were obtained in 1906, making one-quarter of the total from quartzite ores.

Looking at the question from another standpoint, it was found that from ores which carry predominating silver values, and which thus may be classed as silver ores, 19,500,000 fine ounces of silver were obtained. This is somewhat more than one-third of the total output of 56,500,000 ounces. It must be taken into consideration, however, that at least one-half of these ores could be profitably mined only because other metals besides silver were present. Only 1,500,000 ounces were obtained from ores containing no other recoverable metals.

From these data the present small importance of silver mining as a distinct and separate industry is clearly perceived. The pure silver ores are not scarce, but at the present price of the metal they can not be profitably treated unless containing at least about 20 ounces per ton. The lead ores of the Rocky Mountain region are as a rule richer in silver than the copper ores. In the lead ores of the Mississippi Valley silver is either absent or contained in extremely small quantities. Should the quantity of lead ores mined in Colorado and Utah gradually diminish, which seems probable, a corresponding diminution of the silver supply would follow. On the other hand, copper will probably for many years be mined on an increasing scale, and although the copper ores are poor in silver, the great tonnage handled will add much silver to our annual output and compensate for the possible loss from the decrease in the supply of lead ores. The zinc ores do not contain much silver; those of southwestern Missouri are free from silver, and the Rocky Mountain ores rarely contain more than a few ounces per ton.

From all this it is evident that the present supply of silver is assured as long as the mining of lead and copper ores, as well as of quartzose gold ores, continues on the present scale. Should there ever be a scarcity of silver, with accompanying rising price, the Rocky Mountain region beyond doubt contains a large supply of quartzose low-grade silver ores which could be profitably extracted with silver above 70 or 80 cents per ounce.

CONSUMPTION.

The United States consumes only a part of the silver produced. The domestic consumption is divided between coinage and industrial uses for the manufactures and arts. The demands for the latter use have doubled since 1898, and at present the amount consumed is 20,000,000 ounces, of which about 4,000,000 ounces represent old material remelted. For coinage the mints consume variable amounts ranging, during the last ten years, from 4,500,000 ounces to 23,000,000 ounces. In 1906, 7,700,000 fine ounces were coined. The total domestic consumption of the yearly product of the mines may be placed at 25,000,000 ounces. The remainder, about 32,000,000 ounces, is exported As is well known, the larger part of the export is taken by India and China. The demand by India is in the aggregate an enormous sum and is increasing at a rapid rate. For 1906–7 the total imports of silver by India were over 118,000,000 ounces, an increase of 34,000,000 ounces over 1905–6. On the other hand, the generally much smaller demand from China fell off, and during 1906 that country actually exported silver. The larger part of the silver which goes to India is, as well known, permanently lost to our industrial world by hoarding. Since the Indian government has succeeded in establishing the permanent value of the rupee at 16 pence (on basis of 1:21.85) it is likely that the decline in price of silver will be checked, but the supply appears to be so great that a vigorous recovery can hardly be expected.

COPPER.[a]

PRODUCTION OF THE UNITED STATES.

The copper-mining industry of the United States has developed at a rapid rate. In 1888 the production was 226,000,000 pounds of the metal. After eight years, in 1896, it had doubled. After ten years again, in 1906, it had nearly quadrupled, attaining almost 918,000,000 pounds. Reactionary tendencies developed in 1907 and 1908, and the output of the latter year will probably be about 860,000,000 pounds. It is impossible to accurately forecast the final character of the curve of production, but if we draw a straight line from the point on the diagram representing the production of 1883 to that of 1908, we shall with some probability have the trend of the production for future years. It is altogether improbable that the increase will continue at an increasing rate; more likely the rate will gradually diminish; a straight line will probably express its trend for the next ten years, at least. On this basis the production would be about 900,000,000 pounds in 1910, and 1,160,000,000 pounds in 1920. The following table will give a good idea of the growth of the industry since 1845. It shows that the rate of increase during the present decade is considerably smaller than it was during the decades 1881–1890 and 1891–1900:

Magnitude and growth of copper production in the United States from 1845 to 1907, inclusive.

Year.	Production.	Increase.		Average annual increase by decades.	
	Pounds.	*Pounds.*	*Per cent.*	*Pounds.*	*Per cent.*

[a] Decrease.

PRODUCTION OF THE WORLD.

The world's production of copper has also increased rapidly, but not at the rate attained by the United States. From 274,000 metric tons in 1890 it has grown to 711,000 tons in 1907. To this amount the United States contributed, respectively, 118,000 and 386,000 metric tons. The paramount importance of this country is easily perceived.

The world's production, outside of that of the United States, increased as follows:

	Metric tons.
1890	156,000
1895	165,000
1897	182,000
1900	219,000
1905	297,000
1907	325,000

From this it will be seen that the increase was slow from 1890 to 1895, and that it then began to mount rapidly, doubling in the twelve years from 1895 to 1907.

No single country compares in importance with the United States. The supply from the Rio Tinto mines in Spain and Portugal is almost constant at 50,000 metric tons per annum; that of Germany and Chile likewise, with, respectively, 20,000 and 27,000 tons. Australia, Canada, Mexico, Japan, and Russia have shown rapid growth in the copper industry; among these Japan leads with an output of 49,000 metric tons in 1907. For the next few years increased production may confidently be expected from Canada, Mexico, and Russia. Copper deposits of enormous extent are reported to have been discovered in central Africa. Their product is not likely, however, to compete with other sources for five or seven years.

RESOURCES OF THE UNITED STATES.

For many years the bulk of the copper production has been divided between Michigan, Montana, and Arizona. In each of these States the increase has been rapid and continuous since 1880, but for a series of years, beginning with 1891, Montana far exceeded the other two States. In 1895, for instance, Montana produced 50 per cent; Michigan, 34 per cent; and Arizona, 12.6 per cent of the total output. During the last few years there has been a tendency to equalization, caused by the rapid advance of Arizona. In 1907, of a total of 869,000,000 pounds, Arizona yielded 257,000,000; Montana, 224,000,000; and Michigan, 219,000,000 pounds. Utah comes next with a production of 66,000,000 pounds. California yielded 34,000,000 pounds; Tennessee, 20,000,000 pounds; Colorado, 14,000,000 pounds; New Mexico and Idaho each, 10,000,000 pounds; Alaska, 7,000,000 pounds; Wyoming, 3,000,000 pounds; and Nevada, 2,000,000 pounds. These 12 States are the only ones which will have to be considered in more detail. The less important will first be disposed of.

COLORADO.

Colorado can be dismissed in a few words because the copper is largely recovered as a by-product from many mines with mixed ores, chiefly, in fact, from the Leadville mines. The State has no important copper mines and it is not likely that its production will exceed the figure of 1907, when special incentive to the recovery of this metal was given by abnormally high metal prices.

IDAHO.

Idaho has three copper districts of some importance—the Cœur d'Alene, the White Knob, and the Seven Devils. With copper prices at 13 cents the last two districts will probably not be able to attain a large yield. At present the greatest part of the production comes from the Snowstorm mine in the Cœur d'Alene district. With copper at 15 cents, or higher, the reserves of the State will be materially augmented and the present production could probably be increased.

WYOMING.

The State of Wyoming produces copper from the Encampment district, near the Colorado line. The deposits are fairly large and there is probably a considerable amount of low-grade ore in the district. Low-grade copper deposits are known to exist in Albany, Fremont, and Natrona counties. The State will never rank among the greatest producers in the country, but may be able to maintain a production of a few million pounds per annum.

NEW MEXICO.

New Mexico possesses large bodies of low-grade copper ores in the Burro Mountains and at Santa Rita. Exact figures can not be given, but with copper prices at 15 cents the Territory will probably be able to maintain its present output (10,000,000 pounds in 1907) for a long period of years. Many of the other mining districts, especially the Mogollon and the Organ, will continue to contribute to the total output. The copper-bearing sandstones of upper Carboniferous to Lower Cretaceous age are developed in New Mexico upon an enormous scale. They are present in the Zuni, the Nacimiento, the Mora, the Oscura, and many other ranges. Past experience has shown that with copper at 13, 15, or even 20 cents, these extensive deposits can not be profitably worked, except on a small scale for selected rich ores; but with prices above 20 cents they should come into the range of probable resources.

ALASKA.

The Territory of Alaska contains at least three copper districts of importance, the Kasaan Peninsula, Prince William Sound, and the Copper River region. From the first and second districts an output of 7,000,000 pounds was obtained in 1907. The deposits are irregular. The ores of the first district are of low grade but easily smelted. At copper prices of 13 cents the outlook is doubtful, but at a higher rate the peninsula may yield a considerable amount for a number of years. The deposits on Prince William Sound are considered promising, but are too little developed to allow a judgment as to future possibilities. Probably they will furnish a fair amount of copper. The Copper River deposits are likewise as yet in the prospect stage, but may in time develop into an important copper-mining district. The most promising property is at present the Bonanza mine, a large body of high-grade chalcocite ore. No data are as yet available as to its continuation in depth.

TENNESSEE.

At Ducktown, Tenn., the Tennessee Copper Company and the Ducktown Sulphur, Copper, and Iron Company are producing an aggregate amount of 18,000,000 to 20,000,000 pounds of copper per annum. The reserves of ore are believed to be sufficient for at least ten years. It is said that the former company has now developed and produced ore to the extent of 3,300,000 tons. About 389,000 tons of ore were mined by this company in 1907.

We now come to a consideration of the States which at present are of paramount importance in the production of copper. They are Michigan, Arizona, Montana, Utah, Nevada, and California.

MICHIGAN.

Michigan, which up to the present time has been the largest contributor of all the States to the total copper output of this country, began production in 1845 and has been steadily and increasingly productive ever since. The output in 1907 was over 219,000,000 pounds. The entire production has been drawn from the Lake Superior copper district of the northern peninsula, and the productive area is a belt 1 or 2 miles wide by about 70 miles long. Developments are more extensive than in any other copper district. The grade of the ores has steadily declined and now averages only about 1.1 per cent recovered. Costs of operations are extremely low, however, and the greater part of the present output can be maintained under the current copper market. The tonnage of ore that is reasonably assured is enormous and probably exceeds that in any other district; it is now being depleted at the rate of almost 10,000,000 tons annually. One company alone estimates 20,000,000 to 25,000,000 tons remaining in one lode (the "Calumet" conglomerate) in its ground that has been worked since the sixties of last century. Another lode (the Kearsarge) is being mined for 12 miles along its strike almost without break, and to depths on the incline ranging down to about 5,000 feet. A third very important lode (the Baltic) is being found much more extensive than formerly known, and, like the Kearsarge, promises to yield an enormous output before exhaustion. Two other lodes (the Osceola and Pewabic) are of much importance and may be safely counted on for large production for many years. Several of the smaller producing lodes will long continue to contribute to the State's supply, and some of the extensive development in the northern end of the district is likely to bring out important resources.

The conglomerate ores, which so far have yielded more than half the total output and are decidedly richer than the amygdaloid ores, will probably cease to be productive, at the present rate of working and under normal prices, at the end of fifteen years—twenty at most. But the amygdaloid ores, which are much more cheaply worked and in this way offset their lower yield, are able to maintain the district as one of the great copper regions of the world for many years to come. The deepest workings have now attained a vertical depth of practically one mile, and as the workings are extended farther down, the increasing cost of operation and the decreasing grade of ore will ultimately make mining unprofitable. While this condition seems not far in the future at certain local points, its effect on the general output of the district will, to judge from present tendencies, be felt at a very remote time.

Copper is known to occur for many miles beyond the southwestern end of the productive belt, but the development of important resources there is as yet problematical. It is probable that at best that section can achieve important output only under higher prices than can be reasonably expected for many years.

ARIZONA.

The foundation of the present production of Arizona, which in 1907 was about 257,000,000 pounds, was laid in 1873, when mining began in the Morenci district. Within a few years the Bisbee district became a producer and the ores of the old silver district at Globe became chiefly valuable for copper. Shortly afterward the United Verde mine at Jerome became an important producer. The production of these four districts increased steadily and rapidly, and in 1907 they produced jointly over 240,000,000 pounds, or more than the total yield of any other State. While there are a large number of other producing districts in the Territory, of which two or three are of decided promise, these four principal centers of production must be chiefly relied on for many years if Arizona is to maintain her output.

BISBEE.

The Bisbee district produced about 110,000,000 pounds in 1906, and practically all of it came from ores of relatively high grade. Most of the output was from secondary or enriched ores, and was produced at a cost low enough to maintain the district as an important producer with prices decidedly lower than at present. The principal companies are known to have good reserves blocked out, but figures as to tonnage and tenor are not available. There is a fair outlook for adding laterally to the productive area. The lowest workings are about 1,400 feet deep, and the primary or little-enriched sulphide ore of good grade encountered at that depth is an encouraging indication of possibilities.

MORENCI.

The high-grade ores of the Morenci district have been largely exhausted, and for a number of years the chief source of production has been the comparatively low-grade concentrating ores formed by secondary enrichment. The production in 1907 was about 63,000,000 pounds. A large tonnage is still doubtless available for extraction, but at a depth which only in a few places exceeds 400 feet the workable ores give way to the original pyritic deposits that are of too low grade to be profitably worked under any conditions that can at present be reasonably forecast. The ground that is possibly copper bearing has not yet been entirely prospected, and during the past three years of good prices the principal operators have conserved the better-grade ores. But it seems probable that the district has about reached its climax in annual output, and that a sustained period of low prices would cause the production to decline sharply.

At Bisbee and at Morenci the precious metals occurring with the copper are not sufficiently plentiful to have appreciable effect on conditions of production.

GLOBE.

The Globe ores likewise were formerly of high grade, but the district, which produced 35,000,000 pounds in 1907, is relying more and more on its medium and low grade ores. The bulk of the present output is from enriched ore. Lean pyritic ore has been reached at a depth of about 800 feet, but the secondary ore of workable grade has been developed in places to the present maximum depth of about 1,200 feet. There is reason to believe that some of the underlying sulphide ore may be profitably extracted, but as a source of important contribution to the copper supply this is very uncertain. Recently the Miami Copper Company has developed a very important low-grade deposit of the well-known type, consisting of disseminated secondary sulphides. The company estimates 4,200,000 tons of 2.9 per cent ore developed and 2,200,000 tons of probable ore in addition, with good prospect of increasing this tonnage. They estimate that in all probability a total of at least 250,000,000 pounds of copper can be taken from the mine as at present developed at a cost of 9 cents per pound. Production from this property is expected to begin in the near future. In the vicinity of Globe there is without doubt a large tonnage of ore, partly of good grade, not as yet altogether systematically developed. Promised improvement in local transportation and bettered metallurgical conditions resulting from increase of sulphide ores produced in the district will almost certainly be followed by increased production from this outlying territory, but the magnitude and persistence of this supply can not now be foretold.

JEROME.

The Jerome district, in Yavapai County, produced 33,000,000 pounds of copper in 1907. As in former years, nearly all this came from the United Verde mine. The ore body is a great lens of pyrite and chalcopyrite in schists and has been opened by workings to the 1,000-foot level, beyond which depth the ore is reported to continue. There is undoubtedly a large tonnage yet to be extracted above this level. Gold and silver are present to the extent of about 1.4 cents per pound of copper, and the copper percentage is high, the ore ranking with the Bisbee ores as the richest now mined on a large scale in the United States. Prospecting in the surrounding region has not as yet disclosed any other deposits of importance.

OTHER DISTRICTS.

At the Silver Bell district, in Pima County, important developments have been made and improvements are nearly completed to largely increase the production of 1907, which was over 5,000,000 pounds. Contact-metamorphic sulphide ores of both smelting and concentrating grade have been opened and the tonnage exposed is reported to be large. In the Mineral Creek district of Pinal County the Ray Consolidated Copper Company has opened a disseminated chalcocite body in porphyry, and estimates indicate that about 3,000,000 tons of about 2.4 per cent tenor have been already developed and can be profitably worked with copper selling at 12 cents. A large tonnage of low-grade garnet-chalcopyrite ore is reported as existing in the Saddle Mountain region, in Gila County, but it is not certain that it can be worked at the present metal market. A large quantity of low-grade ore consisting of copper minerals disseminated in sedimentary rocks is known in the Grand Canyon region, but development has been slight and no generally satisfactory method of reduction has yet been found for application at recent prices of copper.

These four regions have not yet been studied by members of the Geological Survey, and further definite information is not available.

A few million pounds of copper are produced annually in Arizona incidental to the recovery of precious metals. This will doubtless continue, and the probability is that the quantity will increase somewhat. While this source of supply will be relatively independent of the price of copper, it probably can never be of much importance.

The prospect of discovering new important copper fields in Arizona is perhaps brighter than in any other State or Territory.

MONTANA.

The importance of Montana as a copper-producing State began in 1880 with the advent of railroad transportation to Butte, the only large copper district of the State. Production increased with great rapidity, and in 1887 the district was the most productive in the world. It has held that rank almost steadily to the present time, as Montana led in the production of copper until 1907, when it was surpassed in this respect by Arizona. The production of the State in that year was about 224,000,000 pounds, nearly all of which was derived from Butte. The ore bodies of Butte are secondarily enriched portions of pyritic replacements and impregnations of zones of crushed granitic rock. In the early years the ores were of extremely high copper content and carried much silver. Now the greater part of the production is from rather low-grade concentrating ores, and the recovery from all ores is but little over 3 per cent copper. The yield of precious metals is more than 2 cents per pound of copper. The principal output is from a very small territory, and prospecting in the outlying ground during the last few years has failed, in most cases, to give encouraging results. A large tonnage of ore is undoubtedly still available for extraction, but lean pyritic material has been encountered in a number of places at about the same depth (the 1,600-foot level of certain mines) and most of the good ore bodies that occur at greater depths, down to 2,600 feet, are probably to be regarded as localizations of enrichment along certain easily permeable channels. The cost of producing copper is high and the output at the rate of 1905 and 1906, or even of 1907, probably can not be maintained for a long period on copper at 13 cents per pound.

UTAH.

The production of Utah has increased greatly during the last few years. In 1903 the output was approximately 30,000,000 pounds, while in 1906 it had attained 66,000,000 pounds, with prospect of still further increase. The Utah copper is mainly derived from the Bingham district, though smaller quantities are obtained from the Tintic and Frisco districts. All these ores yield also much gold and silver, and their extraction is therefore to a certain extent independent of the price of copper. A production of about 50,000,000 pounds could undoubtedly have been maintained for a series of years, as new reserves were constantly discovered. The recent discovery and utilization of the low-grade Bingham porphyry ores, probably the largest single body of copper ore known in the United States, will, however, advance Utah still further in the rank of the copper-producing States. The two largest companies which treat this ore estimate the aggregate reserves of ore blocked out or partially developed at 120,000,000 tons, which, provided that all of this ore can be extracted, should yield a very large quantity of copper, besides a considerable amount of gold and silver. The yield thus far is somewhat below 2 per cent copper. The copper can be produced cheaply, it is claimed at 8 cents per pound. The tonnage to be treated per day in the plants of the Utah Copper Company and the Boston Consolidated Copper Company is over 9,000 tons, or 3,150,000 tons per annum. At this rate the ores would last about thirty-eight years. In addition a large amount of ore of somewhat lower but probably workable grade is partly developed.

NEVADA.

Until recently Nevada was of little importance as a copper-producing State, but the development of the Ely and Mason Valley districts have materially changed the outlook. At Ely low-grade but enormously large copper deposits have been opened and will begin production in 1908. The three companies working at Ely, the Nevada Consolidated Copper Company, the Cumberland-Ely Mining Company, and the Giroux Consolidated Mines Company, report an aggregate of about 28,000,000 tons of developed and probable ore containing about 2 per cent copper with some gold and silver. The mills erected will have a total capacity of 4,500 tons per day, or 1,500,000 tons per annum. The proved reserves would therefore last about nineteen years. The total cost of mining and reduction will, it is believed, be low; it is claimed less than 10 cents per pound of copper. It is thought that the output of the Nevada Consolidated will be at the rate of 24,000,000 pounds per annum. In the Mason Valley district near Yerington important bodies of ore have also been opened and will probably soon contribute to the output of Nevada.

CALIFORNIA.

The copper production in California began in Calaveras County about forty years ago, but the industry there soon declined and it was not until 1897, when the Shasta County mines began copper production, that the output of this State became important. The production in 1907 was over 33,000,000 pounds.

SHASTA COUNTY.

The Shasta County copper region, which in 1907 produced about 28,000,000 pounds, embraces four districts within an area about 6 by 20 miles. Rich copper-silver ores were first worked at some of the mines, but these have been exhausted, and practically the whole output is at present derived by smelting massive pyritic ores, which yield on the average about 3.6 per cent copper and nearly 3 cents in gold and silver per pound of copper. The ore bodies are large replacement bodies, mostly in porphyry, and in most cases are flat-lying lenses; in a few cases the ore bodies are more nearly vertical. A very large tonnage is now blocked out and in process of extraction. One company has several million tons practically developed, and four other companies have proved up large reserves. One of the largest bodies has been practically worked out and the limits of most of the others are now known. Additional deposits may be discovered from time to time, for the region has not been thoroughly prospected, but the probability is that the best deposits existing are already known. Some of the mines probably have ore of too low grade to be continuously worked with profit under the current prices for copper, and others are dependent for present operation on the simultaneous production of sulphuric acid from the ores. Under favorable metal prices the production of the region is likely to increase rapidly and then after a number of years to decline sharply.

OTHER DISTRICTS.

The only other copper-producing district of any importance in California is in Calaveras County, where sulphide ore of good grade is found in schist. The production has varied greatly from year to year. In 1907 it was somewhat over 4,000,000 pounds. Details as to the probable future of this region are not available, but the outlook is generally considered good.

There is a long stretch of country in the western foothills of the Sierra Nevada where copper is known to occur mostly as lenticular sulphide bodies in schist or slate. Small production has been made from time to time. At most points developments are meager and the future is unknown, but there is reason to believe that with proper application of capital, improved transportation, and good copper prices, this district might make a considerable output. At the Dairy Farm mine, in Placer County, on this belt, a large body of sulphide ore has been blocked out and extraction will probably begin in the near future. The ore is not of high grade and its extension much beyond the ground thus far developed is not certain.

Small production comes from Inyo and San Bernardino counties, in the southern part of the State, but developments as yet do not warrant relying on that region for an important copper supply.

CONCLUSIONS.

The visible reserves of copper ore in the United States are much larger than those of lead ore. Moreover, they are very much larger now, at the maximum of production, than they have ever been before. And yet, upon perusing the preceding notes it is evident that few companies have reserves for as much as ten years and that only in one case are they believed to be sufficient for forty-five years. On its face this condition seems discouraging, at least when we compare it with the enormous reserves established in the investigation of the coal-mining industry. As has been explained in the general part of this discussion, copper deposits differ so completely in their occurrence from coal beds that known reserves like those of coal can not be expected. Each year will, however, surely find extensions of reserves added to those already discovered and large new deposits of low-grade copper ores will also undoubtedly be opened. These possibilities are well illustrated by the discovery within the last two years of a 7,000,000-ton ore body near the old camp of Globe, Ariz., which one might reasonably suppose to be well prospected.

All these data of available reserves are based on copper at about 13 cents per pound. A large part of them would prove unprofitable to extract should the value of the metal sink much below that figure. Should copper increase to 15 or 20 cents per pound the reserves of many mines would unquestionably be vastly increased. Should it go above 20 cents per pound, still more extensive reserves would be available in the cupriferous sandstones of the Southwest. These conclusions, again, are based on present methods of working and recovery. Should further great improvements be made in these processes the limits indicated by the prices might be materially altered.

The copper resources of the United States are believed to be large enough to respond for a number of years to a demand increasing at the rate of 30,000,000 pounds per annum. It is to be anticipated that should this demand continue for a long period the scarcity of ore would ultimately be felt and result in a rising price for the metal. This again would undoubtedly cause the substitution of other metals, like aluminum, for copper whenever possible.

All these considerations have left the foreign supply out of the question. If recent reports are correct, central Africa contains enough copper to supply the world for years to come.

The whole problem of the ores supply contains so many unknown quantities that a final and definite answer is impossible. In the last analysis, however, it comes down to the question whether it is better for a country to reserve its copper for the future, when its value is an unknown quantity, or extract the ore at as rapid a rate as possible when profit is assured. It is believed that the latter method is the best, if at the same time avoidable waste is prevented.

CONSUMPTION.

Only a part of the copper produced is consumed in the United States; exports have been maintained on an increasing scale for the last thirty years. At the present time some, but not much, copper ore is imported to our smelters. On the other hand, there is a large output of foreign raw copper which is refined in the United States. In 1907 the total foreign copper refined in this country amounted to 248,000,000 pounds, or one-third of the domestic production of refined new copper, which for the same year was 784,000,000 pounds.

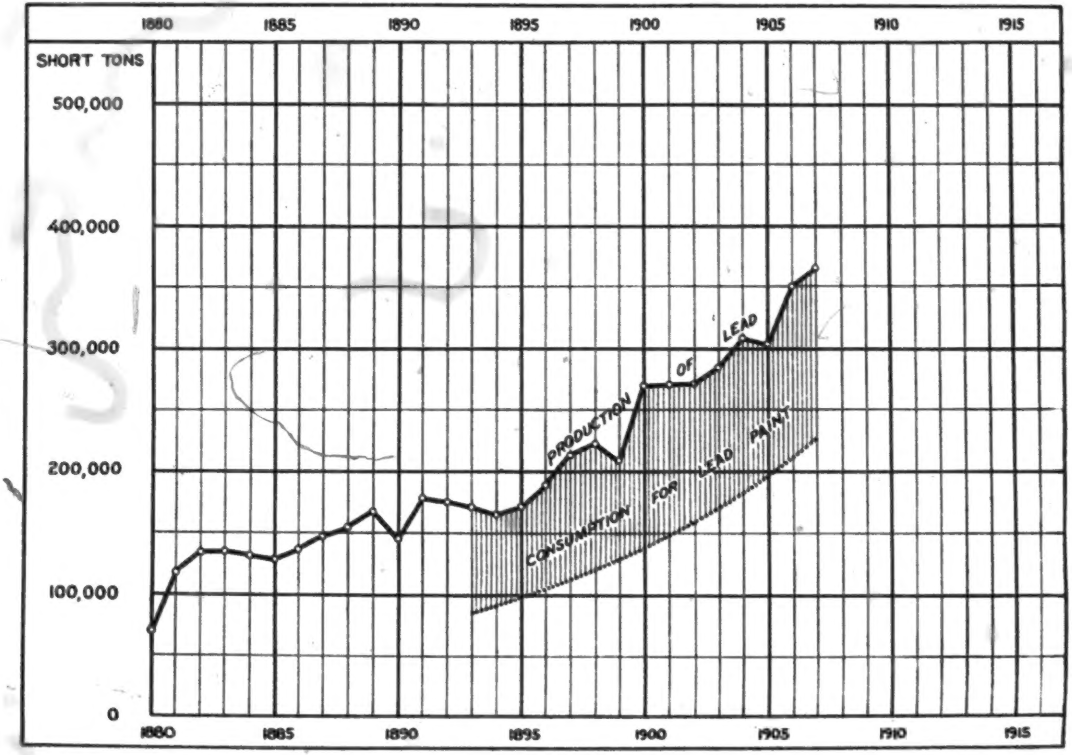
There is no duty on copper or copper ores to interfere with the natural operations of supply and demand. The copper industry has developed in a natural and free manner and no single concern has yet obtained control of the market.

The domestic consumption has increased from about 350,000,000 pounds in 1900 to 685,000,000 pounds in 1906. In 1907 it had decreased to 485,000,000 pounds. To this should be added the consumption of copper recovered from scrap, which was about 60,000,000 pounds in 1907, making a total consumption of about 545,000,000 pounds.

The uses are principally for wire or other electrical purposes, brass, castings, and sheet copper. There is no such great amount permanently lost as in lead and zinc, and a large quantity of scrap will be available with increased production and consumption.

WASTE.

It is not believed that the waste in the mining of copper ore is excessive. Ores too poor to extract at prevailing prices are, of course, left in the mine. But with present methods of extraction, whether timbering, filling, caving, or steam-shovel methods, there is little profitable ore left in the mines.



THE PRODUCTION OF LEAD IN THE UNITED STATES FROM 1880 TO 1907 (IN SHORT TONS).

Much larger are the losses in concentration. The principal valuable mineral in the concentrating ores is chalcocite, which is easily slimed; the loss may be 30 per cent of the metal contained, and it is not always easy to avoid it. Storage of tailings should be enforced, even though in many cases the grade of the ore is so low that there is little present probability of utilization. The waste in copper smelting is not large and the slags are easily available for resmelting; at many reduction works old slags are used as a fluxing material.

LEAD.[a]

PRODUCTION OF THE UNITED STATES.

The diagram shows by graphic method the annual production of lead in the United States for the last twenty-eight years. From 129,000 short tons, in 1885, the production increased at a moderate rate to 1895, when it was 170,000 tons, an average increase of about 3,700 tons per annum for eleven years. The second epoch, from 1895 to 1907, presents radically different conditions. The output rose rapidly and steadily, except for small setbacks in 1899 and 1905, at an average increase of almost 15,000 tons per annum, or about four times as rapidly as in the previous eleven years. In 1895 the total was 170,000 tons; in 1907, 365,000 tons. The increase since 1895 has been at an almost even rate, by average, as clearly indicated on the diagram. Should this rate of increase be maintained, the production of 1910 would be 410,000 tons, and that of 1920, 560,000 to 580,000 tons.

PRODUCTION OF THE WORLD.

In 1907 the world's production of lead was about 965,000 metric tons, while that of the United States amounted to 317,500 metric tons, or about one-third of the whole.

The world's production of lead has not advanced at so rapid a rate as that of the United States. From a total of about 721,000 metric tons in 1897 the production has increased to about 965,000 tons in 1907. If we consider all countries except the United States, the figures for the same period of eleven years would be 541,000 tons and 648,000 tons, an average annual increase of 9,700 metric tons. Upon closer examination it is found that the total production of all countries except the United States increased rapidly—in fact, at the remarkable rate of 23,000 tons per annum from 1897 to 1903. On the other hand, a steady decrease has taken place since that time, from 702,000 metric tons in 1903 to 647,000 metric tons in 1907, equivalent to a rate of 11,000 tons per annum. And this has happened in the face of advancing lead prices.

Considering the foreign supply in more detail, the greatest output comes from Spain (186,000 tons in 1907). The quantity has remained approximately constant from 1897 up to the present time. Spain's resources of lead are known to be great, but it may be seriously doubted whether the present production can be materially increased. Germany contributed about 143,000 tons. Up to three or four years ago a steady increase had been shown in Germany, but in the last few years, in spite of rising quotations, the production has receded. Australia yielded 97,000 metric tons, mainly from Broken Hill, but its output has been decreasing rapidly during the last few years from the maximum of 141,000 metric tons reached in 1903. Practically the same may be said of Mexico. From Mexican ores about 72,000 metric tons of lead were obtained in 1907. The rich ore deposits of Sierra Mojada and other places are being exhausted.

---

[a] Prepared with the assistance of Mr. C. E. Siebenthal, of the U. S. Geological Survey.

The facts given above are significant. They show that the lead deposits of the world are being heavily drawn upon and that, barring new discoveries of great importance, which are somewhat unlikely, a further reduction in the world's output is likely. This reduction will probably be accompanied by a rise in the price of the metal. An advance of a few cents per pound will no doubt create new and large ore reserves in many countries.

RESOURCES OF THE UNITED STATES.

Of the 365,000 tons of lead produced in the United States in 1907, Idaho and Missouri yielded 236,000 tons, or nearly two-thirds. The output of 1907 was divided approximately as follows:

	Short tons
Southwestern Missouri	24,600
Southeastern Missouri	98,400
Idaho	113,000
Utah	62,000
Colorado	51,000
Other States	16,000
Total	365,000

In the following pages the production and possibilities of each State are taken up in sequence.

MISSOURI.

In southwestern Missouri lead is now mainly obtained as a by-product from crude zinc ores which average about one-half of 1 per cent in lead. The heavy lead ores occurred near the surface and are now almost exhausted. The present production of lead is mostly derived from the extensive flat ore bodies in the lower Carboniferous, known as the sheet ground. The portion of the sheet ground which has been mined up to date, say, in the last ten or twelve years, while comprising probably the richest part, constitutes not over the one-hundredth part of the probable sheet-ground territory. Much of this territory is, however, not workable at present ore prices. Large and economical plants will be one of the necessities of the future. Decreased cost of production and higher ore prices may lead to the opening of still deeper disseminated deposits which the drill has shown to exist at Joplin, Webb City, and Granby, and which have also been opened 10 miles south of Joplin. It is believed that the deposits of southwestern Missouri will be sufficient to keep up the present production for fifty years at least.

Although the district of Joplin has been examined in detail by the Geological Survey, it is impossible to measure the extent and richness of the probable ore with any degree of certainty. Any estimate in figures is little better than a guess. As lead is here a by-product of zinc-ore mining, what is said of the zinc-ore supplies holds good also for lead ore.

The production of southwestern Missouri remained fairly constant at 27,000 to 35,000 tons of lead concentrates per annum from 1894 to 1905. In 1906 and 1907 a rapid advance took place, and in 1907 about 42,000 tons of concentrates were obtained.

In southeastern Missouri a pure lead ore is mined, containing an average of about 5 per cent of metallic lead. The important ore bodies occur disseminated at the base of a Paleozoic limestone at depths of 300 to 800 feet in fairly well defined runs or ore bodies, some of which are over 5,000 feet in length. The production has been maintained for many years. In 1892 about 42,000 tons of concentrates and shipping ore were obtained. In 1901 this had increased to 110,000 tons. During the last few years the output has increased rapidly, and in 1907, 157,000 tons of concentrates were produced. This rapid advance is chiefly due to the enlarged plants of the St. Joseph Lead Company and affiliated interests, capable of handling 3,900 tons of ore per day, and to the 2,400-ton concentrating mill recently erected by the Federal Lead Company, which is allied to the American Smelting and Refining Company. No data are available giving the results of the extensive prospecting operations by diamond drills undertaken by these companies, nor has the region been covered by the investigations of the United States Geological Survey. Statements obtained from well-informed engineers indicate that the ore-bearing area covers from 30 to 40 square miles. While this ore-bearing area is large, it is by no means inexhaustible. It is believed that the maximum of production will be reached in a few years. The supply will, however, undoubtedly last for a great number of years, and it is undoubtedly true that there is a great extent of unprospected territory with possibilities of ore deposits at a considerable depth, especially on the south and southwest sides of the St. Francis Mountains.

IDAHO.

In Idaho the Cœur d'Alene district is the principal source of production. Discovered about 1885, this district has rapidly and continuously increased its production until it now exceeds 100,000 tons of metallic lead per annum. The deposits are strong fissure veins in quartzite. The principal properties are controlled by the Bunker Hill and Sullivan Mining and Concentrating Company and the Federal Mining and Smelting Company, the latter affiliated with the American Smelting and Refining Company. The district has been studied by Mr. F. L. Ransome, of the Geological Survey,[a] who expresses his belief that the district gives promise of long-continued activity. Mr. Ransome also states that the ore shoots extend to great depth with remarkably little change in the character of the ore. The Bunker Hill and Sullivan mine, which has distributed over $9,000,000 in dividends, may reasonably be expected to continue its present rate of production for a score or more of years. Similar conclusions apply to several other mines. New discoveries will probably be made, as, indeed, in the last few years two important mines have been added to the producers. The total production of lead and silver will probably continue to increase for several years. The Bunker Hill and Sullivan, the greatest single producer, yielded in 1907 about 35,000 short tons of lead. On its lowest level the ore shoot is said to be as rich as in any of the upper workings, and there seems to be no reason why mining operations could not be extended for several thousand feet below this level. The underground workings have now, according to a recent circular to stockholders, undercut and partially developed 3,000,000 tons of ore, expected to contain 11 per cent of lead and 4.82 ounces of silver per ton, a total of about 330,000 tons of lead. A few of the deeper mines are now, according to Mr. Ransome, extracting ore much leaner than this and may cease to be profitable in a few years. There is also the probability that in general more zinc and less lead will be found as the mines attain greater depth. But on the whole the prospects decidedly encourage the belief that the Cœur d'Alene district will be able to maintain or somewhat increase its present production for some twenty-five years at least.

UTAH.

Utah has long been an important producer of lead, chiefly from three districts, the Park City, Bingham, and Tintic. The Frisco district has lost its one-time prestige in respect to this metal. The total output of Utah now (1907) stands at 64,000 tons, and for a number of years has remained fairly constant. The Park City district is the most productive, yielding about 23,000 tons per annum. The lead ore is contained in strong fissure veins and replacement bodies which promise a long-continued output. The bulk of the remainder, or about 40,000 tons, has until recently been derived from the Bingham and Tintic districts, but in late years the American Fork and Stockton districts have greatly increased their production. Utah is rich in lead ores, and its output bids fair to be continued on the present scale for many years to come. On the other hand, there is little probability of a greatly increased output. Nobody is in position to furnish even approximate figures as to the reserves, and few of the lead mines have, in fact, reserves for more than two or three years ahead.

COLORADO.

Since 1879 Colorado has always been one of the most important lead-producing States. The production reached a maximum when the great ore bodies of Leadville were discovered about twenty-five years ago. It has fluctuated considerably, ranging from 40,000 tons to 80,000 tons of metallic lead between the years 1881 and 1908. During the last few years it has slowly declined and in 1907 was estimated to be 51,000 tons. Leadville has always been the most prominent district and its production was greatest when the enormous bodies of carbonate ore were worked, from 1880 to 1890. During recent years the output of Leadville has remained fairly constant at about 23,000 tons, or one-half of the total production of Colorado. The rich oxidized ores are almost exhausted. The deeper ore bodies are of great size but are poor in lead. It is largely owing to the utilization of zinc ores that Leadville has been able to maintain its production; the tonnage of zinc-lead ores, poor in lead, is now about one-third of the tonnage of the lead ores and the siliceous ores. Undoubtedly a large output of lead can be maintained for many years, but it will probably slowly decrease. The rest of the Colorado lead is mainly derived from Aspen and Creede. The former district is slowly decreasing in importance. Regarding the latter, the information at hand is not extensive, but it is believed that the district is in position to maintain its output for a number of years.

From the preceding it appears that there is little chance of increase in the lead production of Colorado. More probably it will gradually decrease. The State is rather throughly prospected, and the chance of new discoveries is correspondingly small.

OTHER STATES.

None of the other States yield enough to become a seriously considered factor. The total output from them was 16,000 tons in 1907. Probably many districts will increase in importance; others will fall out. For a number of years to come we may count with some confidence on this amount as their aggregate total. The Eureka mines in Nevada, once prominent, are now being reopened, but thus far no ore bodies similar in importance to the old bonanzas have been reported. The railroads now being built in the State will open a considerable territory, which will yield a fairly large amount of lead from newly developed smaller districts or from rehabilitated old districts like Pioche. Discoveries of new lead-producing districts like Leadville or Park City or the Cœur d'Alene are of course always possible, but they do not seem very likely.

Summing up these data, it is believed that the lead production of the United States can be maintained at the present figures for a number of years—possibly twenty years—but that after some such time it would be more likely to decrease. Barring new discoveries of great value, a continued increase of production, like that which has taken place in the United States since 1895, is very improbable. With increasing demands for consumption the price of lead would gradually rise, and in such case of course each cent permanently added to the price of the metal would make available large additional ore reserves, but even at an increased price there is little probability of an indefinite increase on the scale of the last few years.

CONSUMPTION.

For the last ten years the United States has consumed all of the domestic lead produced, and in addition a variable but small amount has been imported. The consumption has practically kept step with the production.

A feature of much interest is that over one-third of the lead is used in the manufacture of white lead and consumed as paint. This feature is shown in the accompanying diagram. In 1907, 135,000 tons of metallic lead were so used. White lead is used more than any other substance for paint, although the manufacture of zinc white and zinc-lead white has taken great steps forward during the last few years. Of course the lead so used is absolutely lost, and it does seem as if for these purposes some other material might be substituted for so valuable a metal, especially when, as shown above, the ore reserves are relatively low. Probably no other nation uses lead paint to the same extent as the United States; partly because here wood construction prevails; partly because our greater prosperity allows the use of more expensive paint. With general substitution of brick, stone, or cement (of which our resources are inexhaustible) for wood (of which our supply is rapidly diminishing), the demand for lead white would greatly decrease. Anything that could be done to encourage this change would be desirable.

SCRAP LEAD.

With increasing production and price a greater quantity of scrap will each year be remelted for consumption. In 1907, according to incomplete returns made to the United States Geological Survey, 25,000 tons of lead were thus returned to consumption; the latter is thus in reality at least 25,000 tons greater than the figures of production would indicate.

WASTE.

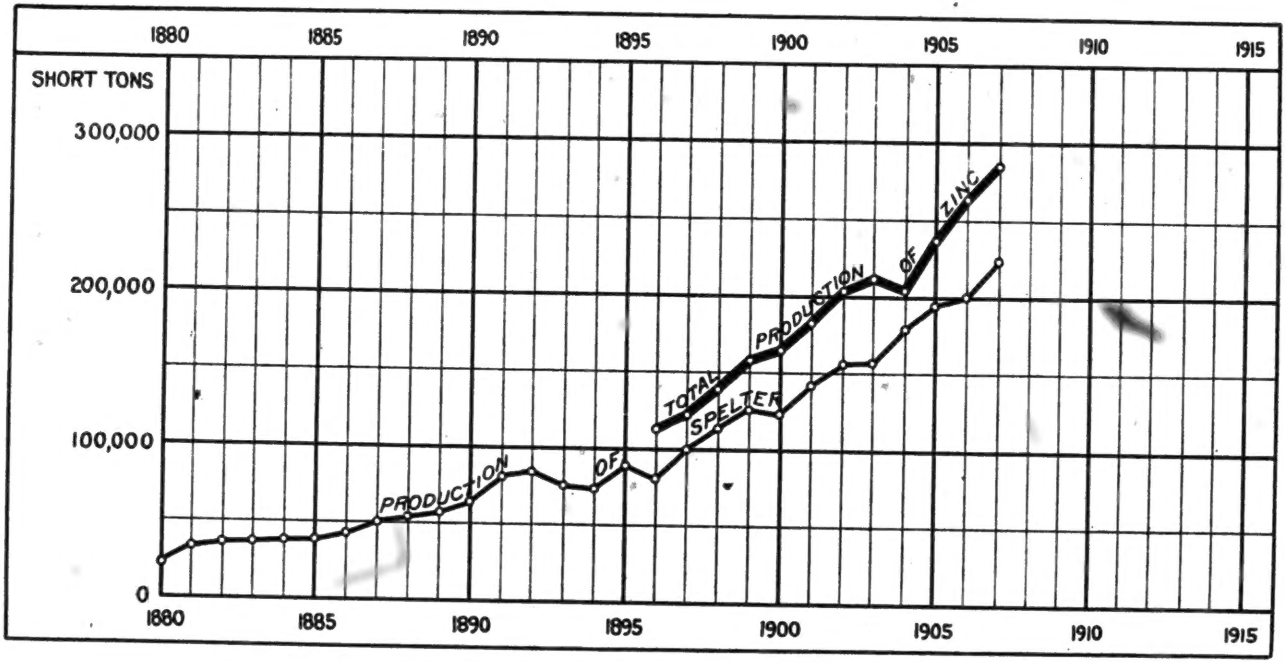
There is little waste in the mining of lead ores. Neither is there much waste in the smelting of the ores; besides, the slags are of course always available for retreatment, if necessary. The loss in smelting and refining is usually estimated as 5 per cent, although this figure is probably somewhat too high.

The greatest waste takes place in the concentration of lead ores. It is not nearly so great as in case of copper and zinc, but doubtless often amounts to 15 per cent. The best way to mitigate this feature would be to compel all owners of concentrating works to store their tailings.

The improvements in both concentration and smelting have been very great in the last fifteen years, and this fact has, of course, enabled the miners to handle lower grades of ore. A lead ore containing 4½ per cent of metallic lead is now worked in southeastern Missouri, and ore containing 5½ to 6½ per cent (with 2 to 3 ounces of silver) in the Coeur d'Alene district. Further reduction in the costs are probable, but not likely to be great as long as the present high scale of wages in the West continues.

TARIFF ON LEAD AND LEAD ORES.

The lead-mining industry has been to a high degree artificially stimulated by the duty on refined lead and lead ores. Under this protection our own resources have been strained to the utmost. We have put a premium on the output of lead and the result is shown in the price of the metal, which is higher in New York than in foreign markets. The control of the market in the United States has not unnaturally fallen into the hands of a trust. Both the smelting and the mining interests have been greatly favored, while the consumer has been paying the bills. Were the duty on lead and lead ore removed the western and central lead-mining districts would no doubt be forced to reduce wages and pay the strictest attenion to reduction of cost. The natural resources would, however, probably be less heavily drawn upon.



THE PRODUCTION OF ZINC IN THE UNITED STATES FROM 1880 TO 1907 (IN SHORT TONS).

Upper line shows total production of zinc as spelter and as zinc in zinc white, manufactured from ore. Lower line shows production of spelter.

ZINC.[a]

PRODUCTION OF THE UNITED STATES.

The zinc-smelting industry in the United States is of comparatively recent origin. From a small beginning of 23,000 tons of spelter in 1880, the production of spelter increased at a moderately rapid rate up to 1896, as shown by the diagram. This total increase in seventeen years was only about 60,000 tons, or at a rate of 3,500 tons per annum. From 1896 a much more rapid rate began. The average increase from 1896 to 1907 was at the rate of 14,000 tons per annum, or from 81,000 tons in 1896 to 223,000 tons in 1907. The rate of increase has been fairly uniform within this period, but was distinctly greater from 1903 to 1907 than from 1896 to 1903, the average annual increase during the former period amounting to 18,000 tons.

All these figures, it should be remembered, refer to spelter; a large part of the zinc ore is, however, used for pigments, chiefly zinc oxide, partly also zinc-lead white. The upper curve in the diagram shows the zinc in pigments added to the production of spelter. The amount of zinc used annually for paints has doubled since 1896 and is now about 60,000 tons. Taking this into consideration it is seen that the total production of zinc in the United States was 284,000 tons in 1907, and that the annual increase since 1904 has been 32,000 tons in 1905, 27,000 tons in 1906, and 21,000 tons in 1907. Assuming that a straight line from 1896 to 1907 represents the average tendency, the production in 1910 would be about 325,000 tons; in 1915, 395,000; and in 1920, 475,000 tons. Should the substitution of zinc oxide for white lead proceed on a still larger scale in the future than in the past, which seems possible, the figures at the years mentioned would be very materially increased.

PRODUCTION OF THE WORLD.

The world's production of zinc has increased since 1896 at a very rapid rate, but not quite at the pace set by the United States. The total production increased from 422,000 metric tons in 1896 to 737,000 metric tons in 1907. The production from all sources, excepting the United States, amounted to 352,000 metric tons in 1896 and 510,000 metric tons in 1907, an average annual increase of 14,300 tons.

The celebrated zinc mines in Belgium are still producing heavily, as are the mines of Silesia and at other points in Germany. New and very extensive supplies of ore are being received in Europe from Mexico and Australia, and deposits of great magnitude are reported to exist in Africa. The successful solution of the problem of ore concentration at Broken Hill, New South Wales, will enormously increase the shipments of Australian ores to European smelters, and it is considered possible that the mines of Germany and Belgium may have to reduce their output to avoid overproduction of zinc.

The United States now ranks first in production, having surpassed Germany in 1907.

---

[a] Prepared with the assistance of Mr. C. E. Siebenthal, of the U. S. Geological Survey.

The production of zinc (spelter and zinc in oxide) in 1907 is divided approximately as follows among the States:

	Short tons.
Missouri	142,000
Wisconsin	20,600
Kansas	14,000
New Jersey	62,500
Colorado	30,400
Other States	14,500
Total	284,000

MISSOURI.

It will be seen that Missouri occupies the most commanding position, producing exactly one-half of the total domestic output. Practically all of this is derived from the southwestern or Joplin district. The ores now of most importance are contained in flat deposits in the so-called "sheet ground," which, at a depth of 150 to 250 feet, underlie a large area in this region. The known sheet ground is constantly increased; the extent of the actual known ore reserves is an unknown quantity; the extent of the area of possible ore is very large. It can be said with fair confidence that deposits of zinc ores underlie 50 square miles of territory, with strong probability that further exploration will add another 50 square miles. The portion of the sheet ground which has been worked during the last ten or twelve years, since such mining was first attempted, is between 1 and 2 square miles. Much of the remaining territory is certainly poor and contains considerably less than 3 per cent of zinc sulphide (including some lead), and whether it can be profitably worked is largely dependent upon royalty to the landowner as well as price of zinc. There is also some probability of opening lower deposits of zinc-bearing ground which have been shown to exist at Joplin, Webb City, and Granby and which now are being worked at Aurora at a depth of 325 feet. Superficial deposits will doubtless continue to be discovered and worked, though probably in lessening number and extent in the future. As the result of special study of the Joplin district by the United States Geological Survey, it is thought that the probable ore reserves will be sufficient to keep up the present production for fifty years at least.

KANSAS AND OKLAHOMA.

The zinc-bearing cherts and limestones extend from Joplin into the adjoining States of Kansas and Oklahoma. In Kansas the future can not be predicted, as the deposits so far developed have not been of sheet formation, but there are possibilities of finding extensive deposits in virgin territory and at greater depth in known localities. In Oklahoma the production is now small, but there are in the Quapaw district at least 12 square miles of ore-bearing blanket breccia. Very promising deposits have been opened at Miami, and the blanket breccia probably extends in this direction, making it reasonably certain that the mineralized area is as much as 20 square miles in extent, most of which will be available mining territory when ore yielding 2 per cent of concentrates can be profitably worked.

WISCONSIN.

According to Mr. H. Foster Bain, the extent of the zinc deposits in Wisconsin is fairly well known. The ore does not, as in Missouri, form extensive flat sheets, but shorter "pitches" and "flats." The zinc ore is usually found below the already mined lead deposits, and drilling operations during the last few years have given encouraging results. The production has increased rapidly and with higher zinc prices will probably increase still further. No estimate of actual or probable ore reserves can be given, but there is little doubt that the present production, with zinc at 5 or 6 cents per pound, can be continued for many years.

NEW JERSEY.

The large and in many respects remarkable deposit at Franklin Furnace is the only occurrence of importance in New Jersey. No recent estimate of the quantity of ore is available, but, according to a report by Nason,[a] the ore body in 1894 contained about 8,000,000 tons. According to the reports of the New Jersey Geological Survey, approximately 2,500,000 tons have been mined since 1904. The figures for the total ore reserves may be rather far off the mark, but they serve to show that the ore body is known to have definite limits and that its exhaustion is probably a matter of fifteen to twenty-five years at the present rate of ore production.

COLORADO.

About 1901 Colorado began to ship zinc ores to the smelters and shortly afterward a zinc smelter was built at Pueblo. The production rose rapidly, and, according to the mine reports of the United States Geological Survey, in 1906 attained 43,000 tons, calculated as probably recovered spelter and zinc in paint. In 1907, when the conditions, at least during the latter part of the year, were less favorable, the production was 30,400 tons. The larger part of this came from Leadville, in which camp the lower levels had disclosed large quantities of ore consisting of pyrite, zinc blende, and a little galena. Recent improvement in concentrating processes had made possible the recovery of this zinc and its separation from the pyrite. Large quantities of zinc also came from the Tenmile, Red Cliff, Aspen, Creede, Breckenridge, and Clear Creek districts. The margin of profit was in many cases small, no payment was as a rule obtained for the silver and lead contained in the ores, and the losses in concentration were great. When the lower prices of 1907 were established the majority of the mines ceased shipments.

No figures of ore reserves even approximately correct are available to the Geological Survey, nor can they be obtained, but there is no question whatever that the resources of Colorado in zinc ores are very large, and that with favorable prices an output much larger than that of 1906 could easily be yielded by the State for a long period of years. The ores occur under entirely differing conditions from those of the Central States. The deposits are fissure veins or irregular replacement ores in limestone, and are nearly always mixed,

---

[a] Trans. Am. Inst. Min. Eng., 1894.

i. e., contain silver, copper, lead, and more rarely gold. Many mines once worked for lead have been impoverished by the prevalence of zinc in lower levels.

OTHER STATES.

Conditions similar to those in Colorado prevail in many of the Western States, notably in Utah and Idaho, both of which shipped a considerable amount of zinc ores in 1906 and 1907. From Park City and Frisco in Utah and from the Cœur d'Alene district in Idaho important shipments were made. New Mexico, though not figuring conspicuously in the production of 1907, has some very large zinc deposits at Magdalena and smaller deposits at many places. Its yield of zinc in 1906 was about 8,000 tons, and with favorable conditions this amount could probably be doubled and be continued for a considerable period of years.

Zinc ores in considerable quantities could be furnished by Arizona and Nevada. Prospecting for these ores has not been especially active in the West. In fact, deposits containing zinc have until within a few years rather been shunned on account of the difficulty of treating such ores in copper and lead furnaces and the difficulty of marketing them as zinc ores with profit. New discoveries may therefore be anticipated.

In conclusion, the supply of zinc at prices of 4 to 5 cents is not very large, and will come chiefly from Missouri and New Jersey. At prices above 5 cents the supply will probably be ample for such length of time as we can reasonably foresee. It is thought that our resources of zinc, especially in the West, have just begun to be developed.

CONSUMPTION.

Since 1876 the domestic production has been sufficient to supply the demand, and the importations have been small. A small amount of high-grade spelter and ore has been exported, mostly from New Jersey. There is, it is true, an import duty on spelter practically prohibiting foreign importations, but on the other hand, during the last three years 25,000 tons of spelter have been obtained per annum from Mexican ores, which is equivalent to about one-eighth or one-ninth of our domestic production. There has been a long controversy about the construction of the law in respect to zinc ores. The case is still in the courts and, pending final decision, duties are still collected, to be refunded later should zinc ores be adjudged duty free.

As already noted, about 60,000 tons of the metal are used per annum for the manufacture of white paint. This amounts to one-sixth of the whole output, and is of course permanently lost. Next in importance comes the metal used for galvanizing, and this consumed, in 1905, 100,000 tons; in 1906, 124,000 tons; and in 1907, 149,000 tons, an increase of 49 per cent in two years. In 1907 this amounted to more than half of the total production of zinc. The remainder of the spelter output is about equally distributed between brass and sheet zinc. All these products seem indispensable for the growth and development of the industries, and it is believed that the consumption of zinc will continue to increase at the recent rate for several years to come.

The zinc industry has been less protected than lead mining and smelting. There is no trust controlling the output or the principal part of the output, and it appears to be in a healthy condition. Free importations of zinc ore will act as a healthful check on the too rapid consumption of our resources, and it would probably be well to allow them in the future.

Much zinc can be recovered from the galvanized products, and this recovered metal, which in 1907 amounted to 13,000 tons or more, will of course increase as the output grows larger.

WASTE.

In no metal industry is the waste more startling than it is in the production of zinc. In mining, Missouri must be considered first. Owing to the occurrence of the ore in flat sheets, it is necessary to leave pillars to support the roof, filling or timbering being too expensive. About 14 per cent of the ore therefore remains in the mine, although, of course, care is usually taken to select the poorer ground for pillars as far as possible. In the West, owing to the expensive treatment and shipment of the ore, much low-grade ore is left in the mine, but this is not necessarily a complete loss unless the mine is entirely wrecked.

In concentrating, the losses are enormous. Somewhat better conditions now prevail, but in many cases at least not more than 60 per cent of the assay value is saved in the concentrating works. From 30 to 35 per cent is perhaps an average loss. Southwestern Missouri has been the chief offender in this respect. While the mining and milling costs there have been extremely low, this has been accomplished at a heavy loss of metal. The miner has not been entirely to blame, for the heavy royalties exacted by the landowners have forced him to adopt these wasteful methods. Lower royalties, better concentration works, and obligatory storage of tailings will help these conditions.

In the smelting of zinc ores the loss is heavier than in any other metal; the average is probably nearly 20 per cent of the assay value, and the loss is heavier in western complex ores, containing much iron, than in Missouri Valley ores. It is claimed that the smelter practice has been behind that of Europe. These conditions are being remedied, but still further metallurgical improvements are most urgently desirable and will be soon attained. The western ores usually contain silver and lead; sometimes also copper. Under present conditions these metals are often wasted, and only under exceptional conditions does the miner obtain payment for them. There is vast room for improvements in the zinc industry, and attention to the matter will materially increase the life of our zinc deposits.

The total loss from ore in the ground to spelter is rarely less than 40 per cent.

THE PHOSPHATE DEPOSITS OF THE UNITED STATES.

By F. B. VAN HORN,
United States Geological Survey.

INTRODUCTION.

The occurrence of rock phosphates in the United States has a very important bearing upon the agricultural industry, since many plants can not exist without the presence of phosphoric acid in the soil. Growing crops deplete the soil of its phosphoric acid, and if no steps are taken to restore this substance the soil must eventually become nonproducing.

Florida, South Carolina, and Tennessee have for several years been the main sources of phosphate in the United States. North Carolina, Alabama, and Pennsylvania have produced phosphate rock, but never on a large scale, and there is at present no production from these States. In 1900 Arkansas entered the field as a producer, and in 1906 a new field was discovered in Wyoming, Idaho, and Utah.

DEVELOPMENT OF THE INDUSTRY.

Phosphate mining began in the United States in 1867 in South Carolina. The existence of the rock had been known since 1837, but the possibilities of its commercial use were not recognized until 1859. According to Otto A. Moses:[a]

> In 1859 Professor Shepard and Col. L. M. Hatch suggested the utilization of phosphatic marls in the manufacture of commercial fertilizers and started a factory at or near Charleston, which was, however, soon abandoned. Remains of their compost heap were utilized by neighboring farmers with good effect long after the war.
>
> At the close of the war Dr. N. A. Pratt, formerly connected with the niter bureau of the Confederacy, visited Charleston with the object of starting sulphuric acid chambers. About this time Dr. St. Julien Ravenel, of Charleston, who had mined marl extensively at Stoneys Landing, on Cooper River, for the manufacture of cements, noticed the nodules, analyzed some of them, and found them to contain much phosphate of lime. He became engaged soon after in the manufacture of commercial fertilizers from foreign phosphate rocks. Then followed the discovery (in August, 1867) which has been of such vital importance to agriculture and the prosperity of South Carolina. Pratt and Holmes (Charleston Mining Company), Ravenel and Dukes (Wando Company), then located territory. The value of the deposits became known; other available beds were discovered, and many persons and considerable capital were soon employed in developing the new industry by mining the crude rock and exporting or manufacturing it on the spot into superphosphates. Later on the beds of many navigable streams were found to be largely paved with the valuable substance.

---

[a] Mineral Resources U. S. for 1882, U. S. Geol. Survey, 1883, p. 512.

Until 1888 South Carolina enjoyed a monopoly of the phosphate industry of the United States. In that year Florida came forward as a phosphate State, with a production of 3,000 long tons. In 1904 the production surpassed that of South Carolina, and Florida has maintained its lead up to the present time.

In 1892 phosphate was discovered in Tennessee, and two years later the production from that State was 19,188 long tons. In 1899 Tennessee went ahead of South Carolina, the production from the latter State having decreased steadily since 1894.

PRODUCTION.

The production of phosphate from South Carolina from the beginning of the industry in 1867 to the year 1888, during which period that State was the only producer, was 4,442,945 long tons, valued at $23,697,019. The following table shows the total production from the United States from 1867 to 1907:

Year.	Quantity.	Value.	Year.	Quantity.	Value.
	Long tons.			*Long tons.*	
1867-1887	4,442,945	$23,697,019	1899	1,515,702	$5,084,076
1888	448,567	2,018,552	1900	1,491,216	5,084,248
1889	550,245	2,937,776	1901	1,483,723	5,316,403
1890	510,499	3,213,795	1902	1,490,314	4,693,444
1891	587,988	3,651,150	1903	1,581,576	5,319,294
1892	681,571	3,296,227	1904	1,874,428	6,580,875
1893	941,368	4,136,070	1905	1,947,190	6,763,403
1894	996,949	3,479,547	1906	2,080,957	8,579,437
1895	1,038,551	3,606,094	1907	2,265,343	10,653,558
1896	930,779	2,803,372			
1897	1,039,345	2,673,202	Total	29,208,141	117,316,002
1898	1,308,885	3,453,460			

Of this amount South Carolina has furnished 11,912,959 tons; Florida, 12,395,731 tons; Tennessee, 4,859,991 tons; and other States, 40,460 tons. In twenty years Florida has produced more phosphate than has South Carolina in thirty-one years.

GEOLOGIC OCCURRENCE.

The phosphate deposits range in age from the Ordovician in Tennessee to the Tertiary in Florida, occurring also in the Devonian in Tennessee and Arkansas, and in the Carboniferous in the Wyoming-Idaho-Utah field.

FLORIDA DEPOSITS.

DISTRIBUTION.

Phosphates occur in a general way along the west coast of Florida, principally in Polk, De Soto, Hillsboro, Pasco, Hernando, Sumter, Citrus, Marion, and Levy counties, although the rock has been found also in Alachua, Suwanee, Lafayette, Taylor, Jefferson, Wakulla, and Liberty counties. There are three classes of deposits in Florida—hard rock, land pebble, and river pebble. These deposits vary in percentage of tricalcium phosphate from 78 per cent to 80 per cent in the hard rock, through 68 per cent to 70 per cent in the land pebble, to about 65 per cent in the river pebble.

Hard rock.—The hard-rock phosphate belongs to the Eocene and the Miocene periods. In the former it consists entirely of a bowlder deposit in a soft matrix of phosphatic sands, clays, and other materials, while in the latter it is also found at many places as a bedded deposit in situ. The bowlders vary in size from 2 or 3 inches to 8 or 10 feet, and lie embedded in all positions, surrounded by sand and clay containing more or less phosphate of lime in finer particles, resulting from a general distribution of the disintegrated portions of the bowlders during deposition. The deposits themselves vary from small pockets to those several acres in extent. The phosphate content of this class of deposits is from 10 per cent to 30 per cent of the mass.

Land pebble.—The pebbles making up this deposit range from minute size to that of a walnut. They are originally white in color, but become dark colored when subjected to water action. They are embedded in sand and are underlain by a stratum of tough, stiff, clayey material known as "bed rock." Above the deposit is an overburden from 1 to 25 feet thick consisting of sand and limestone bowlders. The proportion of phosphate to other rock of this class of deposits varies from 1 to 10 to 1 to 4, or from 10 per cent to 25 per cent.

River pebble.—This class of deposit is very similar to the land pebble and derives its name from its manner of occurrence in the river beds. The pebbles are white to dark brown in color and of about the same size as the land pebbles. They occur in the form of bars in the rivers, and are derived from the formations through which the river flows.

DEVELOPMENT AND PRODUCTION.

The year 1887 marked the beginning of the phosphate industry in Florida. In 1888 the first shipment of pebble phosphate from Peace River was made to Atlanta, Ga. In 1889 the hard-rock phosphate was discovered in Marion County, and in 1890 the land-pebble area was opened up in Polk County. The growth of the industry has been rapid and remarkable, until now Florida is the largest producer of phosphate rock in the United States.

The first production consisted of 3,000 tons in 1888, and twenty years later the output for the year was 1,357,365 tons, or nearly 60 per cent of the entire production of the United States in 1907. Following is a table showing the marketed production and value of phosphate rock from Florida, by years, since the first shipment:

Output of phosphate rock in Florida, based on marketed product, 1888–1907.

Year.	Quantity.	Value.	Year.	Quantity.	Value.
	Long tons.			*Long tons.*	
1888	3,000	$21,000	1899	726,420	$2,804,061
1889	4,100	28,000	1900	706,243	2,983,312
1890	46,501	338,190	1901	751,996	3,159,473
1891	112,482	703,013	1902	785,430	2,564,197
1892	287,343	1,418,418	1903	860,336	2,988,824
1893	438,804	1,979,056	1904	1,072,951	3,974,304
1894	527,653	1,666,813	1905	1,194,106	4,251,845
1895	568,061	2,112,902	1906	1,304,505	5,585,578
1896	495,199	1,547,353	1907	1,357,365	6,577,757
1897	552,342	1,493,515			
1898	600,894	1,847,796	Total	12,395,731	48,043,407

SOUTH CAROLINA DEPOSITS.

DISTRIBUTION.

The South Carolina phosphate beds occur interruptedly along a belt the lower limit of which extends along a meandering line from a point near the source of the Wanda River in Charleston County to the mouth of the Broad River. The belt follows the coast, running back as far as 20 miles from the ocean.

In South Carolina the phosphate rock occurs in two forms: The land rock and the river rock, running about 58 and 55 per cent in tricalcium phosphate.

Land rock.—The land rock is very probably of Miocene age, and consists of so-called pebble rock which is in fact a solid mass from which the calcium carbonate has been leached out and partially replaced by phosphate, leaving cavities which connect and penetrate through the rock, giving it the appearance of being made up of separate pebbles. The rock runs from 1 to 3 feet in thickness, and is overlain by a greensand marl.

River rock.—The river rock is so called because it is mined from the river channels. It consists essentially of the water-rounded fragments of the land rock.

DEVELOPMENT AND PRODUCTION.

As already stated, phosphate rock was discovered in South Carolina in 1867, during which year 6 tons were marketed. From this time on the production increased until 1889, when it amounted to 541,645 long tons. Since 1893 the production has almost steadily decreased, and in 1899 Florida took the lead in the industry. In 1907 only 257,221 tons were marketed from South Carolina. The total production and value of phosphate rock from South Carolina, by years, from 1867 to 1907, is shown in the following table:

Production of marketed phosphate rock in South Carolina, 1867–1907.

Year ending—	Quantity.	Value.
May 31—	*Long tons.*	
1867	6	
1868	12,262

Total	11,912,959	53,221,272

TENNESSEE DEPOSITS.

DISTRIBUTION.

The deposits of phosphate in Tennessee lie mainly in Maury, Hickman, Perry, and Lewis counties, with some deposits in Giles, Williamson, Davidson, Sumner, and Decatur counties.

There are three commercially important classes of phosphate rock in Tennessee: The brown residual phosphate, the blue or black bedded phosphate, and the white phosphate. These range in phosphatic content from 70 per cent to 80 per cent lime phosphate in the brown rock to 75 to 85 per cent lime phosphate in the white rock, although in all three classes are to be found portions which run as high as 90 per cent.

BROWN RESIDUAL PHOSPHATE.

This variety of phosphate occurs mainly in Maury County. It is of Ordovician age, and is the result of the leaching process to which the phosphatic limestones have been subjected. Surface waters bearing carbonic and other organic acids have dissolved and carried away a large part of the calcium carbonate forming the limestone, leaving the calcium phosphate as a residual deposit. The brown phosphate is from 2 to 6 or 8 feet in thickness at various points.

BLUE OR BLACK BEDDED PHOSPHATE.

These deposits are of Devonian age, and show variations from oolitic through compact and conglomeratic to shaly forms. There is also a nodular variety which occurs in a greensand formation immediately overlying the black shale. The bedded deposit occurs in seams varying from 1 to 50 inches in thickness, but where carrying high-grade rock the bed is seldom more than 20 inches thick. The phosphatic content ranges from 30 to 85 per cent. The nodular variety, which is embedded in a greensand matrix, runs about 60 per cent lime phosphate, but it is not practicable to work it except at points where the bedded rock is mined by stripping off the over burden.

WHITE PHOSPHATE.

This rock is of post-Tertiary age, and occurs in three different forms, stony, brecciated, and lamellar. The stony phase contains usually only about 50 per cent of lime phosphate and is not worked at the present time. The lamellar forms were deposited in caves, and are thus of irregular shape and extent. The breccia consists of fragments of Carboniferous chert cemented by lime phosphate. The chert fragments vary from a fraction of an inch to 3 or 4 inches in diameter. The lamellar variety consists of thin parallel layers or plates about 1 inch thick, but several inches long and broad.

The white phosphate has thus far been found only in Perry and Decatur counties. It runs sometimes as high as 85 per cent phosphate of lime.

DEVELOPMENT AND PRODUCTION.

The blue bedded phosphate of Tennessee was discovered in 1893 and was mined until 1896, when the brown rock was found to be valuable. The favorable location of this brown rock led to the cessation of blue-rock mining for the time. The white rock has not as yet been extensively mined.

The total production of phosphate rock from Tennessee from the first operations in 1894 to the end of 1907 is as follows:

Production of marketed phosphate rock in Tennessee, 1894–1907.

Year.	Quantity.	Value.	Year.	Quantity.	Value.
	Long tons.			*Long tons.*	
1894	19,188	$67,158	1902	390,799	$1,206,647
1895	38,515	82,160	1903	460,530	1,543,567
1896	26,157	57,370	1904	530,571	1,745,054
1897	128,723	193,115	1905	482,859	1,633,389
1898	308,107	498,392	1906	547,677	2,147,991
1899	424,109	1,177,160	1907	638,612	3,047,836
1900	454,491	1,328,707			
1901	409,653	1,192,090	Total	4,850,991	15,920,636

ARKANSAS DEPOSITS.

The developed phosphate deposits of Arkansas are on Lafferty Creek, on the western edge of Independence County. The rock itself is light gray, homogeneous, and conglomeratic, with small pebbles more or less angular in form. The phosphate bed runs from 2 to 6 feet in thickness, and varies from 25 to 73 per cent phosphate of lime.

DEVELOPMENT AND PRODUCTION.

The Arkansas phosphates as such were discovered in 1895, but it was not until 1900 that any attempt was made to develop them. At that time the Arkansas Phosphate Company was formed, and a mining and milling plant was erected. After only a few months' operation this plant was destroyed by fire, and it has only been within the last two years that any production has been marketed, and that has been a small one. Analyses show that very little of this rock is high grade, and the field will probably not be operated until 30 to 50 per cent rock can be utilized.

WYOMING-IDAHO-UTAH DEPOSITS.

DISTRIBUTION.

Within the last few years a large area of phosphate-bearing rock has been discovered in the western United States. This discovery is of much importance since it opens a new field in an area which is tributary to the great agricultural region of the Middle West. The phosphate occurs over a considerable area in southeastern Idaho, southwestern Wyoming, and northeastern Utah. It is found in rocks of upper Carboniferous age in a series of shales and limestones, 100 feet thick, within which are several beds of phosphate rock ranging in thickness from a few inches to 10 feet. At the base of the series is a limestone, and 6 to 8 inches of soft brown shale separates this from the principal phosphate bed, which is 5 to 6 feet thick. This phosphate bed is oolitic in character and high in phosphoric acid. There are several other beds ranging from a few inches to 10 feet in thickness, separated by thin beds of limestone or shale, in the series. Usually one and sometimes two of these beds at a given section are workable, and probably some of the others will eventually be mined. The lime phosphate content in the workable beds varies from 65 to 80 per cent, with an average of 72 per cent.

DEVELOPMENT AND PRODUCTION.

The newness of the field, the lack of transportation facilities, and the high freight rates have prevented the development of this phosphate territory to a great extent, although there has been some shipment from Montpelier, Idaho, in the last two years. According to F. B. Weeks,[a] who recently prepared a report upon these phosphates:

> This field embraces the largest area of known phosphate beds in the world, and at some future time it will doubtless furnish a large part of the world's production of commercial fertilizer. The development of intensive farming as a result of the reclamation of arid lands in the West will afford an increasing home market.

PHOSPHATE AS A FERTILIZER.

According to a letter from Dr. W. L. Rasin, of Baltimore:[b]

> The manufacture of chemical fertilizers in the United States began about 1850. In that year Dr. P. S. Chappell and Mr. William Davison, of Baltimore, made some fertilizer in an experimental way. About the same time Professor Mapes was experimenting. Later De Burg utilized the spent bone black derived from the sugar refineries and made quite a quantity of "dissolved bone black" (superphosphate). In 1853 or 1854 Dr. P. S. Chappell commenced the manufacture of fertilizers, as did B. M. Rhodes, both of Baltimore. In 1855 Mr. John Kettlewell, recognizing the fact that Peruvian guano (then becoming quite popular and containing at that time 18 to 21 per cent ammonia) was too stimulating and deficient in plant food (phosphates), conceived the idea of manipulating the Mexican guano, containing no ammonia but 50 to 60 per cent of (bone) phosphate of lime, and called his preparation "Kettlewell's manipulated guano."
>
> While in 1856 the sales of Peruvian guano had increased to 50,000 tons, and of Mexican guano to some 10,000 tons, there was not at that date 20,000 tons of artificial fertilizers manufactured in the entire country. Baltimore was not only the pioneer but the principal market for fertilizers until some time after the civil war.

In 1859 a fertilizer plant was built at Charleston, S. C., by Professor Shepard and Col. L. M. Hatch, but it was soon abandoned. Since the discovery of valuable deposits of phosphate rock in South Carolina in 1867, the fertilizer industry has grown rapidly, and in 1900 there were 478 factories in the United States, with an output of 2,887,004 tons of fertilizer, valued at $41,997,673.

AVAILABLE PHOSPHATE DEPOSITS.

The known phosphate deposits of the United States are distributed principally among four localities: (1) Along the west coast of Florida, going back 20 to 25 miles inland; (2) along the coast of South Carolina, extending 6 to 20 miles inland; (3) in central Tennessee; and (4) in an area comprising southeastern Idaho, southwestern Wyoming, and northeastern Utah. In addition to these areas some deposits occur in north-central Arkansas, along the Georgia-Florida state line, in North Carolina, Alabama, and Mississippi, but these are mainly of low grade and not utilized at the present time. The first three of the important deposits have been worked for ten to thirty years, while the fourth is a new field which has as yet had but a small output.

---

[a] Contributions to economic geology, 1907, pt. 1: Bull. U. S. Geol. Survey No. 340, 1908, pp. 441-447.

[b] Twelfth Census Report, Vol. X, Pt. IV, p. 562.

Owing to very incomplete data any estimate as to available supply of phosphate rock must, at best, be unsatisfactory. Taking South Carolina as the field most likely to first reach the exhaustion point, Florida second, Tennessee third, and the practically untouched deposits of Idaho-Wyoming-Utah last, an estimate of the available supply and possible duration is given, based on the past production.

South Carolina.—By reference to the table of total production (p. —) it will be seen that the output gradually increased from 1867 until 1889, when the largest production, 541,645 long tons, was marketed. Since 1893 the output has decreased at about the same rate as the increase previous to that year. In the twenty-seven years from 1867 to 1893 the production was 7,269,453 long tons, and in the fourteen years since 1893 the production has been only 4,643,506 tons, or 63.8 per cent of the production to 1893. Arguing from these figures, it is safe to say that the amount of phosphate rock remaining to be mined in South Carolina is not more than 3,000,000 tons, but it is possible that by careful deeper prospecting these figures may be increased. At the present rate of production this field has a probable life of not more than fifteen years.

Florida.—The total production of phosphate rock in Florida since the beginning of the industry in 1888 has been 12,395,731 tons. As shown by the table on page 560 there has been a steady increase in production, but since 1904, when the increase in output over the previous year was 212,615 tons, the increase has been smaller each year, until in 1907 it was only 52,860 tons. When it is remembered that the phosphate deposits in Florida are not continuous beds, but rather pockets, and that practically all the phosphate-bearing areas in the State have already been discovered, it appears conservative to estimate an available supply remaining at not more than 15,000,000 tons, or a little more than has already been produced. At the present rate of production the phosphates of Florida would have a life of approximately twelve years.

Tennessee.—The total production of phosphate rock in Tennessee since the discovery in 1893 has been 4,859,991 tons. In 1907 the production was the largest in the State's history, amounting to 638,612 tons. In Tennessee the phosphates exist as brown rock, blue bedded rock, and white rock. The brown rock is the result of leaching processes in an original phosphatic limestone and occurs usually on the surface. The ease of mining and accessibility to transportation have contributed to the rapid working out of this class of rock, but there still remains enough of it to last possibly five years at the present rate of production; that is, about 3,000,000 tons. The blue bedded rock has not been worked considerably in the past, but with the approaching exhaustion of the brown rock a good deal of activity is now being shown. The bedded character of this rock and its continuity over large areas make it certain that large amounts are still available. According to the American Fertilizer for November, a company has been organized and has taken up 16,375 acres of phosphate land, with 10,000 acres under option. An estimate of 1,500 tons to the acre gives approximately 40,000,000 tons, but this estimate is very conservative. The phosphate rock is heavy, weighing about 175 pounds to the cubic foot. Supposing workable phosphate rock 1 foot in thickness to underlie the 26,375 acres, there would be approximately 100,500,000 tons as an available supply in this territory, more than two and one-half times the amount estimated by the American Fertilizer. With the 3,000,000 tons of brown rock estimated, there would be a total available supply of 103,500,000 tons remaining in Tennessee. At the present rate of production in Tennessee this would last about 160 years. But with the exhaustion of the South Carolina and Florida deposits in twelve years the burden of the industry would fall on Tennessee and the western deposits. In case Tennessee furnished all the phosphates for the country, at the present rate of total production, after the South Carolina and Florida deposits are exhausted in twelve years, the Tennessee deposits would give out about 1960. These figures do not include vast quantities of rock running from 25 to 50 per cent lime phosphate, which are not at present workable.

Wyoming-Idaho-Utah.—The production from this field has not been sufficient to warrant mention, nor has enough detailed work been done in the area to afford a good basis for figuring available supply.

F. B. Weeks, of the Geological Survey, has made a reconnaissance report on the district, from which a very rough estimate of the available rock may be made. The phosphate formation consists of phosphatic limestones and shales 80 to 100 feet in thickness, varying in lime phosphate from 65 to 80 per cent in the workable beds to 20 to 50 per cent in the portion not at present workable. This series dips at all angles from 20° to 90°, thus giving a much larger possible tonnage than would be expected from the superficial extent of the deposits. The formation is cut by faults to a very great extent.

The area underlain by phosphate in the western field is almost wholly public land. Only one claim, the Waterloo placer claim, has been patented, but much land valuable for its phosphate deposits has been staked out in claims, of which there are not to exceed 200 in the aggregate. The engineer of the Waterloo property claims 1,000,000 tons of rock in sight above the valley, without taking into consideration the rock underground where the steep dip carries it from the mountain side. There are perhaps 200 other claims on which development work is being done at the present time. If each of these claims is but half as rich as is the Waterloo, they would represent an available supply of 100,000,000 tons in this field, a supply sufficient to furnish the entire production of the United States, based on the 1907 output, for forty-four years. It is to be understood that these figures do not include the immense quantities of low-grade rock which underlie the western field, nor do they take into consideration the quantities which are at present too deep to be profitably worked. With no more reliable figures at hand, this estimate is offered for the high-grade phosphate rock at present actually available in the Wyoming-Idaho-Utah field. Doubtless before the high-grade rock is exhausted some method will be devised for making use of the low-grade rock, which is at present unavailable both in Tennessee and the West.

Arkansas.—Phosphate deposits are known to occur in Arkansas, but they have not been mined to any large extent. They are apparently of low grade, and large quantities are not to be counted on until rock containing 30 to 50 per cent lime phosphate can be utilized for fertilizer manufacture. This material would not, therefore, be classed as available at this time.

EXPORTATION.

In 1907 there were 2,265,000 tons of phosphate rock produced in the United States. Of this amount over 900,000 tons, or about 40 per cent, was exported. It is not difficult to see that, with our steadily increasing population, the time is not very far distant when the farm lands of the Middle West will be burdened to their fullest capacity. It has been shown, as the result of agricultural experiment station work in Wisconsin, Ohio, and Illinois, that in fifty-four years soils of these States in the cropped areas have been depleted of one-third of their original phosphoric acid. This is equivalent to 20 pounds per acre annually. Assuming it to be only half this amount for the 400,000,000 acres of cropped land in the United States, it would require 6,000,000 tons of phosphate rock annually, or nearly three times our 1907 production, to offset this loss, without considering the question of increasing the productivity. With the reclamation of the arid lands of Wyoming and other Western States will come a period of intensive farming, and in order to produce the large crops which will be required of them, these lands must soon have the assistance of artificial fertilizer. We will have enough to do to take care of our own farm lands without shipping our phosphate rock to foreign countries, and in justice to future generations exportation should be stopped.

Total tonnage available.—Following is a table showing the estimated tonnage of phosphate rock available at the present time in the United States.

	Tons.
South Carolina	3,000,000
Florida	15,000,000
Tennessee	103,500,000
Western States	100,000,000
Total	221,500,000

ESTIMATED LIFE OF PHOSPHATE DEPOSITS.

The rate of increase in production for the past twenty years has been 117 per cent for each decade. Assuming that this rate of increase will continue, it will require just twenty-five years to exhaust the available supply of phosphate rock in the United States. The annual production, at the above rate of increase, will be approximately 17,000,000 tons in 1932.

It is hardly probable that the rate of increase in production will be so great as for the past decade, since the agricultural lands of the Middle West do not at present need artificial assistance. But increasing population with its accompanying intensive farming will eventually force these States to the use of fertilizing materials. The reclamation of arid lands in the West will probably postpone the day, but even those lands will early need some assistance to grow the large crops which will be required of them.

Of course the vast amount of low-grade rock which is not now available will be in reserve, and sometime before the exhaustion of the high-grade phosphates we will doubtless have begun to use this rock. The increasing price of the 60 to 80 per cent phosphate will have a hastening effect on the utilization of the present low-grade material. We have the deposits of Arkansas, Georgia, North Carolina, Alabama, Tennessee, and the West, which run from 30 to 50 per cent in lime phosphate, to draw upon after the high-grade rock is exhausted. This class of deposits, especially in Tennessee and the Western States, will afford an enormous tonnage.

There is still the chance of the discovery of more phosphate fields, and probably the Wyoming-Idaho-Utah field will produce far more than estimated, but based upon present available deposits the life of the phosphates must at best be a short one.

FOREIGN DEPOSITS.

Deposits of phosphate rock exist in Algeria, France, New Zealand, Canada, Russia, Spain, Tunis, Belgium, French Guiana, and some of the South Sea Islands. The deposits of France and Belgium are practically exhausted, only those of low grade remaining. Concerning the other countries, no information as to reserve tonnage is at hand except for the three South Sea Islands—Ocean, Pleasant, and Makatea. These islands have deposits which are estimated to contain an aggregate of 60,000,000 tons of high-grade phosphate rock.

UTILIZATION OF THE PHOSPHATES.

From the above figures it will at once be seen that the utilization of our phosphate deposits to the best possible advantage is imperative. Our farm lands must be preserved for future generations. The phosphate rock of South Carolina is practically exhausted; the Florida deposits have reached their maximum production; the output of the Tennessee deposits is on the increase, but this field alone would, at the present rate of increase in production, last only eleven years. There is some phosphate in Arkansas, but it is of low grade; therefore the large deposits of the public-land States must be depended on for the greater part of our phosphate in the future. The conservation of our phosphate deposits can be best accomplished in the following ways:

1. *Correction of wasteful mining methods.*—The waste involved in mining phosphates, especially in Tennessee, should have some attention. In order to get the largest quantity of high-grade rock necessary for the export trade, large amounts of 50 per cent rock are thrown on the dump and wasted. The time is sure to come when 50 per cent rock, and even 25 per cent rock, will be utilized in fertilizer manufacture. Steps should be taken now to prevent this waste in order to avoid a similar mistake when the phosphates of the Western States are mined. Much of the western rock runs from 25 to 50 per cent lime phosphate, and such material should be saved toward the

time when the term "high-grade rock" will come to mean a lime phosphate content of 40 to 50 per cent instead of 70 to 80 per cent as at present.

2. *Utilization of sewage.*—One of the important sources of phosphoric acid to which we must look in the future is the human excrement which is now being wasted through the present systems of sewage disposal. Van Hise says:

> Whitson estimates that the loss in the cities due to man alone is the equivalent of 2 or 3 pounds of phosphoric acid per acre for the entire cropped region of the United States. Supposing this loss to be 2 pounds, this is one one-thousandth of a ton, which amounts for the 400,000,000 acres to 400,000 tons of phosphoric acid, or equivalent to 1,200,000 tons of phosphate rock.

The significance of these figures will at once be seen when it is known that the total production of phosphate rock in the United States for the year 1907 was 2,265,343 tons.

3. *Leasing of the phosphate deposits.*—Only by preventing or materially curtailing exportation can we be assured of the use of our phosphate deposits for our own lands in the future. The following table shows the production and exportation of phosphate since 1900:

Table showing production and exportation of phosphate rock in the United States, 1900–1907.

Year.	Production.	Exportation.	Year.	Production.	Exportation.
	Long tons.	*Long tons.*		*Long tons.*	*Long tons.*
1900	1,491,216	776,220	1905	1,947,190	879,979
1901	1,483,723	624,996	1906	2,080,957	964,241
1902	1,490,314	747,672	1907	2,265,343	900,983
1903	1,581,576	817,503			
1904	1,874,428	849,130	Total	14,214,747	6,560,724

From this table it will be seen that over 46 per cent of the phosphate rock produced in the United States since 1900 has gone to foreign countries. In this connection the American Fertilizer for November gives an account of the organization of the Franco-American Consolidated Phosphate Company, with a capitalization of $7,500,000. The capital stock is fully paid up, and is divided as follows: $5,250,000 for the purchase of phosphate lands in Tennessee, and $2,250,000 for the purchase of fertilizer plants in Europe and for working capital. The company is headed by a powerful syndicate of leading fertilizer manufacturers and bankers of France, Spain, Italy, and Belgium, who will control the stock of the company; and by this organization the fertilizer industry of Europe is expected to be completely under its control.

The company has purchased 16,375 acres of phosphate lands, and has 10,000 acres more under option. Among their plans it is stated:

> The company has contracted all of the export rock it can produce for the next ten years, and has concluded arrangements for the immediate introduction, on a large scale, of the blue rock, both in Europe and in this country.

From this it would appear certain that the phosphate deposits of the United States are to be drained for the benefit of the worn-out farm lands of foreign countries. So far as the deposits of Florida, Tennessee, and South Carolina are concerned, this can not be easily prevented, but the production of the newly opened western fields may be preserved for the United States by retaining in the Government title to all the phosphate rock in the lands now belonging to the United States, and leasing these deposits under appropriate terms. In the lease could be included a clause providing that the lessee shall agree to mine phosphate rock only for home consumption.

If all the lands containing phosphate were reserved pending leasing, it would remove from entry certain lands which might otherwise be occupied by home seekers, and it is therefore necessary to provide for the disposal of surface rights alone. Such a separation of surface and mineral rights would obviate the necessity of creating large phosphate reserves in which the surface lands would be removed from settlement; it would permit the fullest utilization of the land in all particulars. A separation of surface and mineral rights would furthermore insure the proper utilization of all phosphate deposits which may hereafter be found in lands now belonging to the United States.

TENURE OF MINERAL LANDS.

By C. W. Hayes,
United States Geological Survey.

There is unquestionably a strong tendency toward the segregation of mineral properties; it is stronger, however, in connection with some minerals than with others. The tendency is probably greatest in connection with iron ores. The reasons are that the iron-making industry itself has in recent years been consolidated under the control of a comparatively few companies, and these companies have in most cases pursued the policy of securing their own ore reserves. Thus the Steel Corporation probably controls 75 per cent of the iron ore in the Lake Superior and southern Appalachian districts.

The tendency to segregate is less strongly marked in the case of coal. This appears to be due chiefly to the fact that coal mines may be developed on comparatively small capital, and to the further fact that the market for the product is very widely disseminated, whereas iron ore, even when produced independently of the companies owning the furnaces, is disposed of to a relatively few purchasers.

Intermediate between iron ore and coal are deposits of the precious and semiprecious metalliferous ores. The extent to which these are segregated in a few hands is determined largely by the geographic position, although the character of the ore and the necessity for obtaining suitable furnace mixtures is also a factor.

The tendency to segregate in case of the minor minerals is not strong. Thus the production of barite, mica, corundum, graphite, feldspar, pyrite, manganese, etc., comes from a large number of small independent producers. The production of sulphur in this country is a monopoly, not by reason of the segregation of separate properties, but through the possession of a patented method for extracting the sulphur from the deposit. An attempt was made to secure control of the production of salt, but the movement failed. The production of petroleum has remained in a large number of separate companies chiefly because such a condition was most satisfactory to the principal refining companies.

MINERAL RESOURCES OF ALASKA.

By Alfred H. Brooks,
Geologist in charge, Division of Alaskan Mineral Resources, United States Geological Survey.

INTRODUCTION.

A complete description of the mineral resources of any region is possible only when its geology has been exhaustively studied, and even then any quantitative determination of the mineral reserves is often little more than a bold guess. The Alaskan geologic surveys and investigations, begun a decade ago, now cover but 16 per cent of the entire Territory. These, moreover, for the most part have been of a preliminary character, and, while they have yielded important facts regarding the occurrence and distribution of the mineral deposits, they do not furnish the minute knowledge essential to quantitative determination. Detailed surveys and studies such as have been relied on elsewhere for quantitative data on mineral deposits are in Alaska almost entirely lacking, since less than a third of 1 per cent of its area has been subjected to such investigation. Therefore, as 84 per cent of the Territory is geologically almost unknown and less than 1 per cent has been mapped in detail, it will be evident that this statement can be only of a very general character.

The following account of the mineral resources of Alaska is based entirely on the work of the United States Geological Survey, whose reports furnish almost the only sources of information on this subject. In the preparation of this statement the writer has utilized the results of all the geologists and engineers who have worked in this field, and has received valuable assistance from G. C. Martin, C. W. Wright, L. M. Prindle, F. J. Katz, U. S. Grant, C. C. Covert, F. F. Henshaw, P. S. Smith, F. H. Moffit, and Adolph Knopf.

In the lack of comprehensive quantitative data it will probably best serve the purposes of this report to consider the more general problems of geographic and geologic occurrence of the various useful minerals of the Territory. The coal resources will be considered at some length, both because of the importance of the mineral fuel reserves and because the geologic occurrence of coal is such as to permit a quantitative interpretation of the data with a far greater degree of assurance than of those relating to other mineral deposits. The subject of iron ore reserves, of almost equal importance with that of coal, can be but briefly touched upon, because so few facts regarding it are available. But little attention has been devoted to iron ore

by the Alaskan geologists, for there is not a single iron mine in the Territory and at only two localities have iron-ore bodies been prospected. Relatively much more is known about the auriferous deposits, especially the placers, for here the observation of the geologist is supplemented by the many facts developed in the course of mining and prospecting. But the character of these deposits, especially that of the auriferous lodes, makes estimates of mineral reserves of but little value. The same holds true of the copper deposits, which are of too great irregularity to allow even an approximation of the available tonnage. Moreover, though copper ores find a wide distribution in the Territory, they have been mined in only two districts. Most of the copper mines are not over 200 feet in depth, one only having reached 600 feet. Predictions as to permanency of ore bodies at depth in this field, which must form an important element in estimating tonnage, can therefore have no great value.

GENERAL DISTRIBUTION.

The ores and other minerals mined in Alaska up to the close of the year 1907 include gold, silver, copper, lead, tin, coal, petroleum, gypsum, marble, and mineral waters. In addition to these iron, tungsten, antimony, quicksilver, graphite, and peat have been found in deposits that will probably be exploited in the future. Of these only the deposits of gold, silver, copper, lead, iron, coal, petroleum, and peat will be described in this report.

As there are no political subdivisions of Alaska, it will be desirable to refer the distribution of its resources to certain geographic provinces, and these must first be defined. (See Pl. I.) The Pacific province includes the lode and placer districts of southeastern Alaska, the Controller Bay coal and petroleum fields, the copper lodes of Prince William Sound, the copper-bearing lodes and gold placers of the Copper River region, the gold placers and lodes and coal fields of the Susitna and Matanuska basins and of the Kenai Peninsula, and the coal fields and gold and copper lodes of the Alaska Peninsula and adjacent islands, often called southwestern Alaska. This whole coast province is a region of strong relief, and much of it is readily accessible from the waters of the Pacific, open to navigation throughout the year.

The mountain system included within the Pacific province forms a high barrier between the coast and the central province, which is of lesser relief. This central province, drained to Bering Sea by the Yukon, Kuskokwim, and some smaller rivers, includes the gold placers of the Yukon-Tanana region, the Koyukuk, and some smaller districts, as well as extensive deposits of lignitic coal. It is accessible in summer by river steamers, but in winter only by long sled journeys.

Seward Peninsula, forming a distinct province, embraces valuable gold placers, as well as some auriferous and argentiferous lodes, some tin deposits, and a little lignitic coal. It is accessible by steamer only during the summer months.

Northern Alaska is here made to include the high mountains which bound the central province on the north, as well as the region of lesser relief bordering the Arctic Ocean. This field has been but little explored, but it is known to contain some placer gold and bituminous as well as lignitic coal. It seems probable that further surveys will show the presence of extensive coal fields in northern Alaska.

These geographic subdivisions have an important influence on the question of the conservation of the mineral wealth of the Territory, for as the geographic conditions dominate the commercial exploitation of the resources, they determine in a large measure the rapidity with which these resources will become exhausted. For example, the lode deposits and coal fields readily accessible from the Pacific seaboard are being exploited for the use of the present generation. On the other hand, though the development of the placer fields of the central province began nearly a generation ago, large areas are still entirely unprospected, and the coal fields of the same region are almost entirely untouched. The coal fields of northern Alaska are not only entirely undeveloped, but are certain to remain so until the time in the future when the accessible coal of Alaska and the United States approaches exhaustion.

COAL.

[By Alfred H. Brooks and George C. Martin.]

STRATIGRAPHIC POSITION AND COMPOSITION.

The Alaskan coals include lignitic, bituminous (some of which will make good coke), and anthracite varieties. Of these the lignitic and lower-grade bituminous coals are the most widely distributed and, so far as now known, the most abundant, at least half of the known coals being lignites. To offset their lower fuel value the lignites often occur in thick beds and with a large percentage of coal in any given section. Moreover, their geographic distribution is such that they afford an important source of fuel for local consumption in some of the less accessible parts of the Territory.

These coals belong to four geologic periods, namely, Tertiary, Cretaceous, Jurassic, and Carboniferous. In addition to these there are some inferior lignites of Quaternary age, and it is by no means improbable that further investigation may lead to the discovery of coal at still other horizons. Of these four periods only the fuels of the first three promise to have any considerable commercial importance, and all but one of the important coal fields are of Upper Cretaceous or Tertiary age. In fact, a large part of the coal beds have been identified as belonging to the Kenai formation, whose age is believed to be upper Eocene. The Carboniferous and Jurassic coals vary in composition from semibituminous to subbituminous fuel. In the younger coal fields anthracite, various grades of bituminous, and lignitic coals are found.

The following table shows the composition of the coals from different parts of the Territory:

Analyses of Alaska coal.

DISTRIBUTION AND AREA.

The known coal-bearing areas aggregate some 1,202 square miles, while the estimated areas of the coal fields are 12,667 square miles (see p. 581). The distribution of the coal, together with a symbol indicating its quality, is shown on the accompanying map.

Besides showing the actual distribution of the areas believed to be underlain by workable coal beds (marked in black) the map also shows the areas of the coal fields, so far as they are known (marked by stippling). The difference in what is represented by these two symbols is that in the first are included areas in which there is a reasonable degree of certainty that commercial coal beds can be opened up, while the second indicates what is known of the probable extension of the coal fields, and hence defines the areas worthy of prospecting. It should be noted that this mapping does not by any means have the same value throughout the territory, for in some instances it is based on geologic surveys of a high degree of refinement; in others the data include only observations made during a rapid reconnaissance.

The coal fields can be considered under the three general geographic provinces already described: (1) The Pacific slope, (2) the central region, and (3) the northern region. (See map.) In the first are included the lignitic and bituminous fields of southeastern Alaska, Cook Inlet, the Susitna Basin, and the Alaska Peninsula, as well as the high-grade fuels of the Controller Bay and Matanuska regions. About 40 per cent, both of the area known to be underlain by coal and of the estimated area of the total coal fields of the Territory, falls in this province. It includes also at least 90 per cent of the known bituminous and higher-grade coals of the Territory. In considering this percentage of total coal area it must be remembered that this is the best-known part of the Territory, and there is, therefore, less likelihood of future discoveries of coal than in the less explored districts of central and northern Alaska. However, as over 50 per cent of this province is geologically almost unknown, there are possibilities that future surveys may lead to the discovery of more extensive coal-bearing areas.

The central province includes some bituminous and subbituminous coals on the lower Yukon, besides more extensive lignitic coal-bearing fields in the upper Yukon basin, near the coast line of Bering Sea, and elsewhere. Thirty-five per cent of the total known coal-bearing area falls in this province, and about 36 per cent of the estimated coal fields. At least 80 per cent of the central province, however, is almost unknown, so it is likely that further discoveries of coal will there be made.

The northern region includes the bituminous and subbituminous coals of the Cape Lisburne region, as well as lignitic and bituminous coal-bearing rocks in the Colville basin. These fields aggregate 24 per cent of the coal area of the Territory, and the area known to be underlain by coal forms 25 per cent of the total. This is a remarkable showing, in view of the fact that only about 10 per cent of this province has been studied geologically. There is every reason to believe that there are extensive coal fields in this part of Alaska.

THE COAL FIELDS.

SOUTHEASTERN ALASKA.

Though Tertiary (or possibly Upper Cretaceous) coal-bearing rocks are known to cover a considerable area on the southern part of Admiralty Island and on adjacent islands, the included coal beds have only a remote fuel value. The beds are from a few inches to 2 or 3 feet in thickness, and the coal, so far as known, is of a low-grade lignitic character.

BERING RIVER.

One of the two fields containing the largest known amount of high-grade coal lies about 25 miles northeast of the small indentation of the southern shore line of Alaska called Controller Bay. The field is drained by Bering River, from which it received its name. This

Bering River field embraces 21.6 square miles underlain by anthracite and 22.7 square miles underlain by semibituminous and semianthracite coal. The coal-bearing rocks trend to the northeast into the unsurveyed high ranges, and it is quite probable that there are considerable areas in the unsurveyed extension of the coal field or possibly other coal fields beyond the one surveyed.

The workable coal beds in this field vary from 6 to 25 feet in thickness, though local swellings occur, giving a much higher maximum. They are included in a great series of sandstones and shale of Tertiary age (Miocene?) which are closely folded and faulted. In quality the coals vary from an anthracite, with 84 per cent of fixed carbon, to a semibituminous, with 74 per cent of fixed carbon (see p. 571). The field includes some coking coal. There is no good harbor at Controller Bay, though plans have been made for building a breakwater. Another scheme of obtaining access to the coal is by constructing a railway from Cordova Bay, a good harbor lying 100 miles to the west. This railway is now (1908) about half completed.

COOK INLET.

Lignite-bearing Tertiary rocks occur widely distributed in the Cook Inlet region. These are usually little disturbed, but locally are considerably folded and faulted. The largest areas of coal-bearing rocks in this field occupy the western part of the Kenai Peninsula and are in pare buried under a cover of Quaternary gravels. It is not impossible that the entire Cook Inlet depression may be underlain by the coal-bearing formations.

The best-known part of this field lies adjacent to Kachemak Bay on the north, where 2,000 to 3,000 feet of coal-bearing rocks are exposed. These contain an aggregate thickness of over 60 feet of workable coal beds, the thickest of which is about 7 feet. Lignite in workable seams has also been found at Port Graham and Tyonek.

Though the Kenai Peninsula was the scene of the earliest (1854) coal-mining venture in Alaska, the output has been only a few thousand tons. These coals, in spite of their accessibility to tide water, can probably not compete with the higher-grade fuels, such as those of the Matanuska field. It seems probable that the coal reserves in the Cook Inlet region are very large, for the area of the coal field is estimated at 2,565 square miles.

MATANUSKA REGION.

The Matanuska coal field shares with that of Bering River the preeminence in the present fuel situation in the Territory. This field lies about 25 miles from tide water at Knik Arm, a northerly embayment of Cook Inlet. As, however, Cook Inlet is frozen during the winter months, the distance to tide water must be measured to the eastern side of Kenai Peninsula, about 150 miles.

The known commercially valuable coals of the Matanuska are included in folded and faulted rocks of Tertiary (Eocene?) age, including shales, sandstones, and conglomerates aggregating 3,000 feet in thickness. The coal-bearing series has been traced for 50 to 60 miles along the Matanuska Valley, but much of it is buried under a heavy blanket of Quaternary gravels. At the western end of the district the bituminous coal, which seems to form the main body of the field, appears to pass into a lignite, while there is some evidence that the same coal is represented by an anthracite at the eastern end of the belt. This anthracite may, however, belong to an older coal-bearing formation.

The commercial coals of the Matanuska field vary from a subbituminous to a semibituminous. There is also some anthracite, but of this less is known. It is evident from the facts in hand that there is a large amount of high-grade bituminous coal in this district. The beds vary from 5 to 30 feet in thickness.

So far as at present known, the total area underlain by commercial seams aggregates 46.5 square miles. As, however, much of the field is covered by gravels and as it has not been surveyed in detail, the coal-bearing area may be much larger. The total area of what may prove to be coal-bearing rocks is approximated at 900 square miles.

A railway is under construction which will lead to the opening of this field. This will bring about the development of the high-grade fuels, of which there is a large quantity. The lignites lying to the west of the Matanuska field will not now bear shipment until the coals of the higher fuel value approach exhaustion. As there is believed to be a very large amount of lignitic coal in this general province, it will be an important element of the ultimate fuel reserves of the Territory.

ALASKA PENINSULA REGION.

The widely distributed coal of the Alaska Peninsula and adjacent islands is in part of Cretaceous and in part of Tertiary (Eocene) age. It is chiefly lignite, but some good bituminous coals occur in this field. The rocks in which the coal beds occur are gently folded and locally, at least, considerably faulted. The total area of the coal fields of this province is estimated at 980 square miles, while that known to be underlain by coal is 61 square miles. About one-half of the coal-bearing area and about one-third of the probable coal field is lignitic, the balance varying from subbituminous to bituminous in quality. Coal has been mined in this field at Chignik and Herendeen bays and on the island of Unga for local use, but the total output has been only a few thousand tons. These coal fields are all readily accessible from good harbors and will form one of the early available fuel assets of the Territory when the demand for coals of this grade warrants their exploitation.

YUKON REGION.

The coals of the Yukon, including bituminous and subbituminous, together with a large amount of lignite, are for the most part of Tertiary (Eocene?) age. Some of the bituminous may, however, be of Upper Cretaceous age. The Tertiary lignitic coal beds typically occur in association with conglomerates, sandstones, and shales, usually only little deformed, but sometimes profoundly folded and faulted. The bituminous coals, which are confined to the lower Yukon, occur with finer sediments, which have been gently folded and somewhat faulted.

The lignitic coal beds occur up to 20 feet in thickness, the bituminous in beds from 2 to 3 feet. These comparatively thin seams have not encouraged exploitation, in spite of the high price of mineral fuel in this central region, but a small production has been made for the use of the Yukon River steamers.

Coal-bearing beds are so widely distributed in the Yukon region that it will not be feasible to give an account of all the occurrences. The three largest fields are (1) Nulato region, (2) Nenana region of the lower Tanana Valley, (3) Washington and Coal Creek belt of the upper Yukon. Of these the Nulato field contains the best coal, while the Nenana is the most extensive and has the thickest beds. The total area known to be underlain by coal in the entire region is 264 square miles, while the coal fields may embrace 2,000 square miles or more.

These Yukon coals will have a high value for local use when the scant supply of accessible timber has been exhausted. There is a constantly increasing demand for power in the placer districts, and this can be met only by developing the water powers, which are not extensive, or by utilizing the coals. The low fuel values and the difficulties of transportation of these coals will probably lead to their local transformation into electric power, to be transmitted to the mining camps. The location of some of the lignite fields with reference to the placer fields is well suited for this purpose.

That a large amount of lignite in excess of any future local demand that can now be foreseen occurs in the Yukon region can not be denied. So far as exportation is concerned, it is certain that the low fuel value of these coals and their inaccessibility will lead to their conservation until the fuel supply of other regions approaches exhaustion.

SEWARD PENINSULA.

The known coal-bearing areas of Seward Peninsula do not exceed a few square miles, and the quality of the coal is of a low grade. This coal, however, is worthy of mention, because it can probably be locally utilized to furnish power for mining purposes, and hence conserve the higher-grade coals which are now being brought in from outside sources. This appears to be a good example of the way a local supply of lignite may reduce the consumption of higher grade fuels. Its success will depend on the development of economical means of utilization of these low-grade fuels, so as to bring them within the sphere of commercial practice and permit their substitution for higher-grade fuels transported from a distance.

NORTHERN ALASKA.

Geographically, the known coal fields of northern Alaska fall into three groups: (1) Cape Lisburne, (2) the Colville Valley, (3) Wainwright Inlet. Coal has also been reported to occur between these areas, as well as east of the Colville River. The Cape Lisburne field includes the Corwin and Cape Beaufort districts.

Three coal-bearing formations are recognized in this northern field: (1) lower Carboniferous (Lisburne formation), made up of slates, shales, and limestones, with some high-grade bituminous coals, and having a thickness of 500+ feet; (2) Jurassic (Corwin formation), including at least 15,000 feet of shales, sandstones, and conglomerates and containing a large number of subbituminous coal beds; (3) Tertiary (Kenai formation?), made up of conglomerates, sandstones, and shales, with lignitic coal seams. The two lower formations are considerably folded, but the Tertiary beds are, as a rule, only little disturbed.

The total area known to be underlain by coal aggregates 302 square miles, while the coal fields, roughly outlined from the data in hand, include some 3,000 square miles. The scant evidence at hand points to the conclusion that a survey of this northern region will show very large coal fields in this part of Alaska.

A little mining of coal for local use has been done in the bituminous field near Cape Lisburne and in the lignitic field of Wainwright Inlet, but the region as a whole is practically untouched. It is certain that there will be no extensive mining in this northern field for a generation or two to come. These coals are too inaccessible to invite exploration, either under the present demands or any that can now be foreseen.

THE COAL RESERVES.

INTRODUCTION.

It will be evident from the facts presented that there are few data on which even an approximate idea of the available tonnage of Alaskan coal can be based. Of the 1,238 square miles believed to be underlain by coal, less than one-quarter has been surveyed in sufficient detail to yield any quantitative data whatever. Even where such surveys have been made, a large factor of uncertainty is introduced either by the folded and faulted condition of the coal beds, which exists in some fields, or by the lack of definite knowledge of the continuity of the coal beds in others. There must, therefore, be a very large element of uncertainty in the tonnage estimates of the 300 to 400 square miles of surveyed coal fields. Moreover, in Alaska there are practically no available data from private sources, such as the results of extensive mining or prospecting operations, which have formed an important element in the estimates made of the mineral resources in the States.

The estimates of tonnage to follow were made on the following basis:

1. No beds less than 3 feet thick were assumed to be workable or contributed to the tonnage.

2. The depth of workability was assumed to be 3,000 feet in the case of the highest-grade coal (anthracite, semianthracite, semibituminous), 2,000 feet in case of the better bituminous and subbituminous coals, such as those on the lower Yukon and at Cape Lisburne and on the Matanuska River, and 1,000 feet in the case of the poorer subbituminous and all the lignites.

3. The tonnage was computed by the following formula: Tonnage = area of bed to limit of workability (square miles) × thickness (inches) × sp. gr. × 72,600.

4. The specific gravity was assumed to be 1.30 for lignite, 1.35 for bituminous, and 1.38 for the high-grade coals.

5. Bering River field: A certain percentage of the coal-bearing rocks is shown by the average sections to consist of workable coal beds. This percentage of the computed bulk of rock to limit of workability gave the estimated tonnage.

6. Nenana coal field: As for Bering River, with the necessary change for percentage of coal in rocks.

7. Matanuska coal field: Each bed was estimated separately according to its average thickness, length, according to a safe assumption of continuity, and width on the dip to the limit of workable depth.

8. Lisburne fields: The Corwin district was computed like the Matanuska, length of beds being assumed to be the distance from the shore to the edge of the area colored on Collier's map. The Beaufort district was assumed to have one-half the tonnage per square mile of the Corwin district.

9. Yukon field: Each bed figured as in Matanuska, but the beds were not assumed to extend in any case more than 1 mile in each direction from the mine or prospect where they had been exposed, except in the Washington-Bonanza district, where a continuity of 50 miles on the strike was assumed.

10. Cook Inlet field: Computed as for the Matanuska.

All the other fields were estimated on the basis of a most conservative estimate of thickness of coal underlying the field and an area believed to be a safe minimum. Neither in this case nor in any of the others was the coal assumed to go beyond where we have reliable information from members of the Survey concerning it. The areas used in making the last class of estimates are consequently very small and are subject to a possible immense extension in the light of subsequent work.

Estimate of tonnage and areas, Alaska coal fields.

Total subbituminous	4,060,300,000	260.7	1,995
Lignite:			
Pacific coast	2,173,100,000	237.0	2,938
Interior region	4,228,000,000	264.5	2,003
Arctic slope	1,003,200,000	93.0	1,736
Total lignite	7,404,300,000	594.5	6,677
Summary by provinces:			
Pacific coast	6,265,800,000	357.5	5,115
Interior region	4,303,100,000	432.5	4,493
Arctic slope	4,535,600,000	312.2	3,059
Grand total	15,104,500,000	1,102.2	12,667

The incompleteness of these figures can best be illustrated by some examples. The Bering River field may be extended into the mountains and have many times its present known area. If the entire eastern and western extensions of the Matanuska Valley are underlain by coal beds, as may be the case, it will increase the tonnage of this field many times that used in the present estimate. In the Cook Inlet and Susitna regions the estimates for tonnage are based on a coal field of 30 to 40 square miles. As a matter of fact, it is not improbable that the whole Cook Inlet-Susitna depression may be underlain by coal-bearing rocks at no depth prohibitive of mining. If this is the case, this coal field might embrace 10,000 to 20,000 square miles.

In view of these facts, it is perhaps conservative to multiply the above figures by 10 or even by 100 to arrive at an approximation of the fuel reserves of this vast unexplored region. This is especially true of the lignite reserves, for there are known to be very extensive fields of low-grade coals in Alaska.

PRODUCTION AND CONSUMPTION.

Though an attempt at mining coal on Cook Inlet in 1854 by the Russians was the first mining undertaken in the Territory, yet the total output up to the present time has been very small, as indicated in the following table. In 1907 there were four productive coal mines in Alaska.

Production of coal in Alaska, 1888–1907.

Year.	Short tons.	Value.	Year.	Short tons.	Value.
1888–1896 [a]	6,000	$84,000	1903	1,447	$9,72
1897	2,000	28,000	1904	1,094	7,22
1898	1,000	14,000	1905	3,774	13,20
1899	1,200	16,800	1906	5,541	17,97
1900	1,200	16,800	1907	10,139	53,60
1901	1,300	15,600			
1902	2,212	19,048	Total	37,507	296,0

[a] The production for 1888–1896 is estimated on the best data obtainable. That for the years subsequent to 1896 is based for the most part on data supplied by operators.

The smallness of the output is chiefly due to two reasons: First, because up to a decade ago, when the rapid advancement of the gold-mining industry began, the local demand for coal was very small, being confined to that of the canneries and shipping interests and the Treadwell mine, which could be supplied at low cost by the fuels brought from Vancouver Island or Washington. Second, the existence of extensive bodies of high-grade coal in Alaska, geographically situated so that it could be exported, has been generally known only for a few years. Since the discovery and surveys of the Controller Bay and Matanuska regions there has been much activity looking to the development of these two fields. As, however, the marketing of this coal requires the construction of 150 miles of railway in one field and 100 miles of railway or 25 miles of railway and possibly an expensive breakwater in the other, the progress of exploitation is necessarily slow. Moreover, the uncertainty of obtaining title to coal lands, which still exists, has made capitalists rather guarded in furnishing the money necessary for these enterprises.

Though the Territory has produced annually only a few thousand tons, the consumption of coal during the past decade has rapidly increased. The following table presents the available statistics regarding consumption of mineral fuels in Alaska:

Shipments of coal and coke to Alaska, July 1, 1903, to June 30, 1907.[a]

[a] Monthly Summary of Commerce and Finance, Bureau of Statistics, 1902–1906.

SUMMARY AND CONCLUSIONS.

The advancement of copper and gold mining, construction of railways, etc., will cause a constantly increasing consumption of coal. It would appear to be in accord with a policy of conservation of mineral fuels to meet this demand from the local supply. Every ton of coal or barrel of petroleum shipped to Alaska by steamer or rail entails a certain amount of fuel consumption for transportation. Moreover, this long carriage is commercially possible only for high-grade fuels, while for local consumption the large supply of lignites of lesser fuel value can be utilized. For example, many of the Alaskan river steamers, now using California petroleum as fuel, could be supplied by the local lignites. This would prevent a double waste: (1) The more valuable fuel is consumed instead of the more abundant lignite, and (2) as the petroleum is brought nearly 4,000 miles by steamer, fuel is used for its transportation. The utilizing of the coals in the Yukon region as a substitute for wood would also conserve the scant supply of timber.

Again, the use of the local coking coals for the reduction of the copper ores will effect a saving of mineral fuels. At present the copper ore is shipped a distance of 500 to 1,500 miles, while if it were smelted near its locality of production 70 to 90 per cent of the material could be left behind, with a corresponding saving of fuel used in transportation. Another saving would be brought about in the case of Alaska steamers now carrying coal from the southern ports for the round trip, if the local fuels were utilized for the return journey.

Discussion of the future utilization and conservation of Alaska's coal supply can best be made by considering separately the same three geographic provinces under which the coal fields have been described: (1) The Pacific slope, (2) the central regions, (3) the northern region. These will here be considered in the reverse order in which they have been given.

The northern coal fields lie in a region tributary to the Arctic Ocean, which is locked in the ice for all but two or three months in the year. Some lie close to the seaboard; others far inland. While little is known of the fuels of this region, all the facts available point to the conclusion that this province contains very extensive coal fields. These mineral fuels are in a region where there are practically no industries and with little promise that any will be developed and the coals are unavailable until the more accessible mineral fuel supply of the world approaches exhaustion. To bring them to a harbor open throughout the year would mean the construction of at least 1,000 miles of railway. Such a haulage, leaving out all other considerations, is of course prohibitive for any present fuel demand. Moreover, these coals are not needed, nor likely ever to be, for any local use, except some of those at Cape Lisburne, which may be utilized for local shipping, and some others which may be used by the scant Eskimo population, now that the supply of driftwood is approaching exhaustion.

The fuels of this northern region can, therefore, be regarded as conserved by the geographic conditions until future generations may have to draw upon them. They can consequently, for the most part, without injury to any existing commercial interests and without retarding the development of the country, be placed under such legislative provisions as will permit their utilization only under such restrictions as the future conditions of the mining industry shall demand.

The coals of the central region are in part accessible to rivers navigable during the summer months and in part lie near the proposed railways from the Pacific to the Yukon. There also remains a considerable percentage but little more available to the present generation than the fuels of the northern fields. These coals are chiefly lignitic in character and, under no demand which can now be foreseen, could be utilized for export to other districts. To bring them to the States would require a railway haulage of 400 to 500 miles and then transportation by steamer for 1,000 to 1,500 miles in addition.

On the other hand, the development of these fields to supply the local demand will conserve (1) higher-grade fuels now imported from great distances and (2) local supply of timber. While little is known of the amount of coal available in this central province, there is every reason to believe that it is far beyond any local demand of the future.

The conservation of the coal of the Pacific slope province is a more complex problem, both because of the high grade of some of the fuels and of their greater accessibility. While none has yet been exported, the great demand for the high-grade bituminous and anthracite coals, such as are found in the Controller Bay and Matanuska regions along the Pacific coast, will lead to their exportation as soon as railways make them accessible. It is probable that the market for these coals will for a long time exceed the production, which will greatly stimulate mining activity once the transportation problem has been solved. When the coals are put on the market, they will probably curtail, if not entirely cut off, the demand for the lignitic and lower-grade bituminous coals which are so abundant in the Pacific coast province of Alaska. Therefore the production of the high-grade fuels will effectually conserve those of lesser fuel value for the present. Some of these low-grade fuels, however, are so accessible and so abundant that future demands and strong competition may lead to wasteful methods of mining, provided they are all permitted to pass into unrestricted private ownership.

The reserve of these anthracite and bituminous coals of the Pacific slope, while it can not now even be approximated, in all probability is far below that of the lignites. It seems probable that an extensive area of the high-grade fuels may be found among the high mountains and glaciers to the northeast of the present known limits of the Bering River field. If such be the case, this will be another locality where the geographic conditions will prevent mining until there is far more demand for the fuel than at present. In the Matanuska there is probably also a large quantity of coal under the Quaternary coating of gravel. Making allowances for future discoveries, however, the high-grade fuel is not abundant, considering the demand for it.

From the standpoint of conservation and economic utilization, the possibility of intense competition between the coal of the Bering and Matanuska fields and that of Puget Sound is the danger point in the prospective situation. If each field develops only to the extent of supplying the demand for the kind of coal which it best can furnish, then the immediate use of the coal will be legitimate and economical. But if the individual fields develop beyond the demand of their respective proper markets—if the Bering River field produces more than the needed supply for steamship, smithing, and local railway and smelting needs and of domestic anthracite, if the Matanuska produces more than is needed for its local railways and smelters, for bunker coal at its tidal terminus, and for shipment to the Pacific coast coke ovens, and if the coal from other fields invade these markets—there is sure to be ruinous competition, which may lead to cutting prices with the sole object of destroying all competition and establishing a general monopoly. In such ruinous competition as has existed in some of the eastern fields the coal fields will be robbed of the more cheaply minable coal at the cost of the destruction of larger amounts which will be left in the ground so crushed and buried that it can never be recovered, coke for distant shipment will be made by wasteful processes at the mines instead of shipping the coal to points where both the coke and the by-products can be used, coal will be coked which would better be used for other purposes, and the waste by consumption en route will be extended to the Alaska coals.

If these high-grade fuels, some of which make excellent coke, are not exploited, several conditions will probably be brought about:

First. The west coast of the United States will probably continue to draw heavily on the fuels of British Columbia, Australia, and Japan, and to the amount imported will conserve its own supply.

Second. There will be an increasing demand for fuel oils, which, while it may not affect the production, will stimulate the search for new oil fields.

Third. The west coast will probably continue to rely on the East for its pig iron and steel, for in the absence of good cheap coke—except as Alaska can supply it or the processes of coking coals are improved—the local supplies of iron ore will not be utilized, unless, possibly, by electrical methods of smelting. As a concomitant to this, the iron ore and coking coals of the East, which are of the most value to the nation, being nearest the centers of the population, will be correspondingly diminished.

Fourth. What has been said of the relation these coals bear to the development of an iron industry on the Pacific coast is to a lesser extent true of copper smelting. Without the use of Alaska coke either the copper ores will be transported to British Columbia or Puget Sound or the coke will be brought to the copper deposits. In either case there is a loss in transportation. While it is true that these factors will affect the copper-mining industry and lead to the exploitation of only the richer deposits, yet the past few years have shown that it is economically possible to bring either the coke to the copper or the copper to the coke.

Fifth. Certain loss of fuel in transporting eastern coals to the west coast for certain purposes where their use is imperative will continue. This is, however, a small item, as the total tonnage of eastern coals to the West is insignificant.

Sixth. There will be no local supply of high-grade coals on the west coast for the use of the navy.

In considering the above facts it must be remembered that these Alaska bituminous and anthracite coal fields can be made accessible only by the expenditure of a very large amount of money. The millions of dollars necessary for the development of these fields will not be forthcoming unless provision be made by which a large tonnage of coal will be made available.

PEAT.

Peat is found in nearly every part of Alaska except in the high ranges. The humidity of the Pacific coastal zone and the consequent luxuriant vegetation favors the accumulation of peat. Southeastern Alaska is heavily forested and often has dense growth of underbrush with a flooring of moss. In southwestern Alaska timber is entirely absent, but all the lowland and much of the upland regions are covered with moss, grass, and small shrubbery. The prevailing humidity in both these districts favors the accumulation of vegetable refuse. Though there has been no prospecting for peat in this part of the Territory, deposits are known at least 15 to 20 feet in thickness and are believed to be of good quality.

Central and northern Alaska have a much smaller precipitation. Here, however, the soil is nearly everywhere mantled by a dense blanket of moss and other vegetation. This is especially striking in the extensive timberless areas or tundras which lie along Bering Sea and the Arctic Ocean. In these two provinces the subsoil is usually frozen, which retains the waters at the surface. The moss, except in excessively dry weather, is usually saturated with water. All these conditions, which promote vegetable growth and retard evaporation and oxidation, are favorable to the formation of peat. As a matter of fact, there is nearly everywhere a layer of peaty material underneath the soil. In some natural exposures peat deposits have been observed in these provinces having a depth of 30 to 40 feet. While the widespread surface layer of peat is of an inferior quality, some of the deeper-lying beds are probably of high grade. There are no data whatever at hand to estimate the available supply of peat. As, however, it is found in every part of the Territory and on the great tundras of the north, occupying at least a quarter of the Territory and comprising layers of greater or less thickness, the supply must be enormous and possibly exceeds that of the entire United States.

In the presence of more easily available fuel there has been no occasion to utilize any of the peat beds, so practically nothing is known of their fuel value, extent, or thickness, except what has been stated. Probably the only place in Alaska where this mineral fuel has been exploited is a peat bed saturated with petroleum residue, near Cold Bay, on the Alaska Peninsula, where the material has been used for fuel at the neighboring oil drills. Here, however, it is the petroleum residue rather than the peat which gives the deposit its chief value.

The peat deposits have at present no value, since lignitic and better-grade coals are too widely distributed to encourage the use of a less available fuel. The time appears also very remote when these peat deposits (except at localities where coal is absent) will be utilized. Certainly recourse to the peat will take place only when the more valuable mineral fuels are not obtainable.

PETROLEUM.

[By G. C. Martin.]

Petroleum may exist in the rocks at many places in Alaska, but at only four localities are the known indications sufficient to justify drilling. Wells have been drilled at three of these localities, but petroleum has been obtained in quantity at only one of them. In all of these the petroleum is of the high-grade variety, suitable for refining, like that from Pennsylvania. These four will be briefly described.

The Katalla field is situated near the mouth of Copper River, in latitude 60° north, longitude 144° west, or about 1,250 miles northwest of Seattle and 400 miles northwest of Sitka. The rocks in this field consist of Tertiary shale, sandstone, and conglomerate. The structure is complex, the rocks being steeply and intricately folded and cut by faults. These conditions would raise doubt concerning the existence of bodies of oil if it were not for the abundant seepages and the presence of oil in the wells. As it is, they increase the cost and other difficulties of drilling and make it entirely impossible to estimate the area of the probable oil-producing territory.

Sixteen wells have been drilled in the Katalla field. The result has been a moderate production of oil from one well and the demonstration of smaller quantities in three others. As only a small part of the area in which the presence of seepages suggests an oil field has been drilled, the proof of the existence of any considerable volume of oil is yet to be made.

The Cook Inlet oil fields are about 320 miles west of Controller Bay on the middle part of the west shore of Cook Inlet. Seepages are here numerous and prolific, but though several wells have been drilled, none has yet proved successful. This field is in an area of Jurassic rocks which are chiefly shales and sandstones. The folding is much more moderate than at Controller Bay, but many faults are present. The relation of the occurrence of oil to the geologic conditions has not been discovered, and hence the areas of possible oil-producing territory are entirely problematical.

At Cold Bay, on the Alaska Peninsula, 160 miles southwest of the Cook Inlet fields, there are many large seepages and several wells have been drilled, none of which has produced more than traces of oil. Here, as in the Cook Inlet field, the rocks are chiefly Jurassic shales and sandstones. The structural conditions are not unlike those on Cook Inlet.

Near Cape Yakataga, 75 miles east of Controller Bay, many large seepages are reported, but owing to the unaccessibility of the region no drilling has been attempted. These seepages are located on Miocene shale and sandstone which are steeply folded.

Summarizing, it may be said that the occurrence of oil is suggested under considerable areas in Alaska, but the presence of profitable oil pools has yet to be shown. The low price of oil on the Pacific coast and the high cost of drilling in Alaska make any attempt to develop the possible Alaska fields at present an unattractive proposition.

All considerations point to the desirability of conserving the Alaska fields until the decline of the California and Mid-Continent fields. When Alaska oil is utilized it should be for refining, and the burning of crude Alaska oil should be discouraged.

IRON ORES.

There being now practically no demand for iron ores on the west coast, such ores have not been sought for in Alaska. The only iron which has been found is that discovered incidentally in prospecting for other minerals, and thus far this has been chiefly magnetite, occurring at only a few localities along the Pacific seaboard. The following note on these deposits has been prepared by C. W. Wright:

> Magnetite is the only iron ore that has been found in southeastern Alaska in commercial quantities. This ore occurs in large bodies, forming contact deposits along the contacts of diorite and limestone on Prince of Wales Island,

where it is associated with the copper deposits, and occurring as magmatic segregations associated with basic intrusive rocks at several points along the mainland coast.

At the copper mines of Prince of Wales Island a considerable tonnage of magnetite carrying from one-half to 1½ per cent of copper has been developed which can not be profitably mined as a copper ore. However, if there were a market for the iron in these ores, the copper could be readily separated mechanically and the deposits mined with profit. The surface showings of magnetite in this copper district are very large, and the estimated tonnage, with a depth of only 30 feet, is about 3,000,000 tons of magnetite. There is, of course, a much greater amount of possible ore, concerning the extent of which almost nothing is known. These ores for the most part contain practically no phosphorus or detrimental impurities, and may be classed as Bessemer ore.

Explorations have been begun to develop magnetite deposits near Haines, on the mainland coast of Lynn Canal, but little is known as yet of their extent or the character of the ores.

U. S. Grant, in his study of the copper deposits of Prince William Sound, noted some hematite ores, but could not determine whether the ore was present in commercially valuable deposits. He also reports the occurrence of magnetite associated with pyrrhotite on Prince William Sound and with chalcopyrite near Seward, on the Kenai Peninsula. His investigations, on the whole, do not encourage the idea of the presence of workable iron ores in this district.

In the Iliamna Lake region there are some copper deposits which from accounts, appear to be of similar origin to those of Prince of Wales Island. With these is said to be associated a large amount of magnetite. So far as known, iron-ore bodies have been found at only one place in the interior. At this locality, which is near the head of the Nabesna River, there is a 2½-foot vein of magnetite which occurs in a limestone near the contact with an intrusive.

The conditions of occurrence of both types of southeastern Alaska magnetite deposits probably repeat themselves along other parts of the Pacific coast line, so that there is a probability that similar bodies of iron ore occur elsewhere. Though the evidence is very scant, it is not impossible that Alaska may have important iron-ore reserves.

GOLD.

INTRODUCTION.

Mr. Lindgren's general report on precious-metal resources of the United States, contained in this volume, emphasizes the fact that no definite statement of the gold reserves is possible. If this be true of the United States, it is far more so of a little-known region like Alaska, where the auriferous deposits have been found in widely distributed districts, usually separated by extensive areas, often but little prospected, sometimes almost unexplored. Moreover, except in southeastern Alaska, the auriferous deposits thus far developed are primarily those of the alluvium, and there has been little search for lodes. Therefore, in most of the gold-placer districts the possibilities of developing an auriferous lode-mining industry are almost unknown.

Geologic survey and investigation, when executed with sufficient thoroughness, lead to definite results concerning the distribution and occurrence of auriferous deposits. If a region has been mapped in detail, the geologist can outline with a fair degree of certainty those areas worth prospecting for gold. Such investigations, however, can be interpreted quantitatively only to a very limited degree in reference to placers and are practically worthless for the purpose of forecasting the gold content and reserves of undeveloped lode deposits.

The actual valuation of developed lode deposits can, of course, be carried only to the limits of the mine workings, which permit the blocking out and sampling of the ore bodies. Such an investigation can be made only at great cost and is properly the function of the mine owner and not the federal geologist.

Placer deposits, whose values are far more regular of distribution, admit of a rough valuation by the geologist; but even in the case of placers the quantitative determination of gold contents in any given body of gravel can be arrived at accurately only by extensive excavations are drilling, and by sampling. This also is evidently the function of the mine owner and not of the federal geologist. Most Alaska placer miners have done so little careful prospecting of their properties as to make their statements in regard to metal contents of but little service in estimating the placer gold reserves. Such data as are available have been carefully compiled by the Geological Survey, but while they may have value in forecasting the direction of future mining development, they are far too inexact and incomplete to admit of more than a bold guess at the gold reserves. Any estimate made at the present time can not take into account the latent possibilities of the hundreds of creeks which, though unprospected, are believed to lie within the gold-bearing area.

In the following account emphasis will be laid on the subject of general distribution and occurrence of the auriferous deposits, because it is believed that such data form the most important element in the valuation of these deposits. Given this information, together with a statement of past production, the technician at least is able to draw his own conclusions.

GEOLOGIC AND GEOGRAPHIC DISTRIBUTION.

The known gold deposits of Alaska can be grouped into three general types: (1) Gold occurs near the contacts between granitic or other igneous intrusions and altered sediments. (2) It occurs in metamorphic schists. (3) It occurs in association with Mesozoic or Tertiary volcanics. Nearly all of the auriferous lodes which have thus far been productive are of the first type, while the second appears to be typical of most of the important placer districts. Examples of the third type have been so far limited to only a few localities. There is some evidence to indicate that the source of the gold of the placers occurring in areas of schistose rocks may be in veins which bear a genetic relation to, as well as a close association with, igneous intrusives. If this proves to be generally the case, it may be found that the deposits assigned to the first two groups may be practically identical in origin.

Most of the auriferous deposits occur in rocks which have been more or less highly altered, but the metamorphism in the placer districts has usually been more pronounced than in lode districts. There are no considerable areas of metamorphic rocks known in Alaska which are not locally more or less auriferous, so that the distribution of these rocks is one of vital importance to this discussion. The metamorphic terranes vary in age from Cambrian or pre-Cambrian to Carboniferous and possibly Triassic. There are also some altered Cretaceous beds which are locally auriferous. While in Alaska their geologic age has little direct bearing on the question of the distribution of gold, yet the most important gold fields now developed are in regions where the rocks belong chiefly to lower Paleozoic or older terranes.

Three considerable belts of metamorphic rocks traverse the Territory. One of these skirts the Pacific seaboard, embracing the auriferous lode and placer districts of southeastern Alaska (see map, Pl. I), the Prince William Sound copper district, and some small gold-bearing areas lying in between. Its southwestward extension is found in the Kenai Peninsula and on Kodiak Island, where it includes some placer and lode deposits.

A second belt stretches southwest from the international boundary, near the famous Klondike district, and includes the Fortymile, Birch Creek, Fairbanks, and other gold placer-bearing areas. Its extension is probably to be sought in the little-explored region lying between the lower Yukon and the Kuskokwim, and may include the newly discovered placers of the Innoko Valley.

The third belt lies north of the main Yukon Valley, includes the gold placers of the Chandalar, Koyukuk, and Kobuk districts, and may find its continuation in the auriferous metamorphic rocks of Seward Peninsula.

In addition to these broad belts thus defined, there are some smaller areas in which gold has been found, such as those of the Nizina, of the Chistochina, of the Yentna, of the Bonnifield, and of the Kantishna districts. These, with others, which will not be enumerated, have yielded some placer gold.

SOUTHERN ALASKA.

The auriferous deposits of southeastern Alaska have been investigated by C. W. and F. E. Wright and A. C. Spencer, from whose reports the following data are drawn: This province is the one in which the close association of the metalliferous lodes with the intrusives is most strongly marked, and where this relation was first worked out. It appears that the strongest mineralization lies close to the western margin of the great intrusive masses of the Coast Range. Similar intrusives are, however, widely distributed in isolated stocks throughout the coastal region of this part of the Territory and its adjacent islands, and these, too, have been found to be mineralized at a number of localities. As there are hundreds of miles of these contacts, and as but few of them have been carefully prospected, the chances of finding additional auriferous lodes appear to be good. At the same time it should be noted that the mere fact of mineralization does not imply the existence of valuable deposits, and that, in spite of the fact that this part of Alaska has been the scene of active mining for nearly thirty years, only the Juneau district has furnished any considerable gold output, and this has chiefly come from the three mines of the Treadwell group. In the Ketchikan district, embracing the southern part of southeastern Alaska, there has been some exploitation of auriferous lodes. Though some of these have carried high values, they are all comparatively small, and many have proved not very persistent.

The value of the total gold output of southeastern Alaska from 1880, when mining first began, to the close of 1907, was nearly $40,000,000, which has come chiefly from the lodes. Its future as a gold producer is promising, yet, excepting the few developed mines, there is but a small tonnage of ore in sight. With the densely forested conditions that prevail, the search for ore bodies has been much impeded, and in spite of its accessibility the region can not be said to have been carefully prospected. There is therefore little on which to base predictions of future production, except the geologic conditions which are favorable to the discovery of new ore bodies. The deepest workings (1,600 feet in the Treadwell mine) indicate a persistence of gold content in deposits of this type which is encouraging.

ST. ELIAS RANGE.

Auriferous sands whose materials have been derived from the metamorphic rocks of the St. Elias Range have been found and mined in a small way at a number of localities. These and what is known of the rocks of this range suggest that here may be a locus of future gold mining, but the facts at hand do not permit a definite statement.

KENAI PENINSULA AND KODIAK ISLAND.

Auriferous gravels have long been known to occur on the Kenai Peninsula. In fact, it was here that the Russian mining engineer Doroshin found the first placer gold (1884) known in Alaska. The placers of the northern part of the Kenai Peninsula have been productive since 1895, with an aggregate output valued at about $2,000,000. For several years, however, the production has fallen off, and it appears that the richest of the known gravels have been exhausted, though there are extensive bodies of alluvium carrying low values. The gold has been derived from metamorphic rocks, and intrusives appear to be absent. The same geologic conditions appear to prevail throughout the eastern part of the peninsula, and other discoveries may be made. Both in the Kenai Peninsula and on Kodiak Island, which lie in the same general geologic province, some auriferous lodes have been found. The accessibility of this region would permit the mining of low-grade ores, so that there is a possibility of a gold production from this district even after the placers have become exhausted.

SUSITNA BASIN AND ALASKA RANGE.

Auriferous gravels are widely distributed in the Susitna basin and have been found on both flanks of the Alaska Range. It is only within a few years that workable placers have been found, and the entire production does not exceed a few hundred thousand dollars in value. The geologic conditions in the Alaska Range are in some respects very similar to those of southeastern Alaska and are therefore favorable for the occurrence of auriferous deposits. In view of the unexplored condition of much of this field, it is useless to attempt any forecast of its future from the mining standpoint.

COPPER RIVER BASIN.

There are two widely separated auriferous areas in the Copper River basin. The northern area lies on the south flank of the Alaska Range, and the southern area is a western extension of the St. Elias Mountains. What has been said of the future of mining in these ranges applies to these districts excepting that there has been some gold output from these, and they will undoubtedly continue to produce, as systematic mining has hardly commenced.

ALASKA PENINSULA AND ADJACENT ISLANDS.

The Alaska Peninsula region furnishes the only developed example of the third type of auriferous deposits, namely, an occurrence in volcanic rocks. This is at the Apollo mine, which has made a considerable production. Recent information leads to the opinion that there are other similar types of deposit in this general region. If such prove to be the case, this district may also swell the gold production, though at present its entire annual output is confined to a few thousand dollars taken from beach placers and a small production from lode deposits.

YUKON BASIN.

Mining was begun in the Alaska Yukon about 1887, when the Fortymile placers were discovered, but the total production up to the time of the discovery of the Fairbanks placers in 1901 was less than $6,000,000 in value, whereas the production for 1901 to 1907, inclusive, is valued at nearly $30,000,000.

The best known and probably most valuable of the placers of the Yukon basin lie in the so-called "Yukon-Tanana region," embracing an area of some 40,000 square miles between the two rivers, of which about half falls in what may be designated as the "auriferous zone." Within this province lie the Fortymile, Birch Creek, Fairbanks, Rampart, and Hot Springs districts, as well as some smaller ones, all of which have produced placer gold.

This province is the best example of gold occurring in metamorphic schists, but some of its auriferous deposits appear to be intimately associated with intrusive rocks. So far as known, the geologic conditions which prevail in the developed placer districts persist over much of this field. Certain it is that auriferous mineralization is widely distributed, for fine particles of gold occur nearly everywhere in the alluvium. Much of the Yukon-Tanana region is so inaccessible as not to attract the large operator. While the bonanza hunter has hurriedly traversed most of this region, the scarcity of bed-rock exposures and other conditions adverse to prospecting prevent such hasty investigations from yielding definite results as to the presence of gold deposits. Even in the best-known and most accessible parts of the region new discoveries of placers are constantly being made. All these facts indicate that this may be one of the largest placer-gold reserves of the Territory.

The data bearing on the gold contents of the gravels known to carry values have been carefully assembled by L. M. Prindle and F. J. Katz, and these indicate a reserve of about $100,000,000 in value for the ground which has been more or less prospected. This is certainly a conservative estimate, for it takes into account only the auriferous gravels which can probably be mined under the present conditions, or those that will prevail during the next few years, and does not make any allowance for the large unprospected areas.

A belt of schists lying north of the Yukon, extending from Chandalar Valley into the Koyukuk Valley, has been found to be auriferous. Mining has been going on in the latter district since 1899, with a production of probably over a million dollars in value. This field is one of very high cost in mining, and there are probably more extensive deposits with a smaller gold tenor than those now exploited. The Chandalar district has made but a small production, mining having been begun in 1906.

Placer gold has been found at several places in the lower Yukon basin, notably on the Melozikakat, on Ruby Creek, and on the Innoko. Too little is known of the character or extent of these deposits to permit any statement as to their future importance. They prove, however, a wide distribution of the auriferous deposits and indicate possibilities in the way of future discoveries.

Nowhere in the Yukon basin has there been any lode mining, and systematic prospecting for auriferous veins has hardly been inaugurated. As a rule, the mineralization in the schists appears to be disseminated rather than concentrated, but there are exceptions to this rule. Some lode deposits have been found which, in a more accessible region, could probably be profitably exploited. The subject of the future of lode mining in this field does not admit of solution from the data in hand.

SEWARD PENINSULA.

Placer mining was begun on Seward Peninsula in 1897, but it was not until 1899 that the annual gold production exceeded $100,000 in value. The total output of gold up to the close of 1907 was over $44,000,000 in value. Practically all of this gold was taken from the placers, for only one small lode mine has made any considerable production, though a few tons of ore have been taken from several others.

The auriferous deposits of the peninsula can be roughly outlined as occurring in two general belts. One, about 40 miles wide, stretches a little north of east and skirts the southern shore line of the peninsula, embracing the gold placers of Nome, Solomon, and Council. This belt has been traced about 120 miles. The second belt stretches from the neighborhood of Port Clarence to Kotzebue Sound, a distance of about 140 miles, with a width of about 40 miles. In this belt are included the auriferous gravels of Teller, Kougarok, Inmachuk, and Kiwalik. As outlined, these belts embrace an area of about 10,000 square miles. In addition to these areas, evidence of mineralization has been found in the extreme western part of the peninsula, which includes the cassiterite, galena, and other ores of the York region.

In describing the geographic distribution of the mineral deposits of the peninsula, it is not intended to imply that there is any great regularity in their occurrence. As a matter of fact, the distribution of the valuable minerals within these zones is very irregular. The placer gold seems to have been derived, for the most part, from contact zones between massive limestones and various types of schists. P. S. Smith's recent investigations show that other forms of auriferous deposits are those found in black siliceous slates and those in chloritic schists. Other types of mineral occurrence are those of cassiterite, galena, and other ores which are found in association with granitic intrusives near the western end of the peninsula and which have recently been described by Adolph Knopf.

While the types of mineral occurrence might be multiplied, for they include copper, antimony, tungsten, and other ores, what has been stated is sufficient to show that there is great variety in the form of mineralization. It also indicates that, in spite of the fact that there is now but little lode mining there is sufficient ground to believe that such an industry may be developed as to make it necessary to take it into account in estimating the gold reserves.

Though the Seward Peninsula auriferous gravels have been far more prospected than those of the Yukon-Tanana region, yet quantitative data of their gold contents are exceedingly scant. These data, however, were carefully compiled some years ago, and deductions made from them regarding the placer-gold reserves. Estimates were made by two different methods. By one the gold contents of auriferous gravels was valued at $265,000,000; by the other, $325,000,000. It can not be too often repeated that such computations are no more than mere approximations, for they are based on certain assumptions as to the gold tenor of the gravels, etc., which do not now admit of proof. These reserves appear to be two or three times as large as those estimated for the Yukon-Tanana region. This is due to the fact that in Seward Peninsula the data seemed to justify an attempt at an estimate of gold tenor for the entire body of auriferous gravels, while in the Yukon-Tanana region the information at hand only warranted an estimate of the auriferous gravels of the productive areas.

STATISTICS.

The systematic collection of statistics of gold production for Alaska was begun only in 1905, and the distribution of the output previous to that year is only an approximation. In the preparation of the following table the best available data have been used. In this table of production the Pacific coastal belt includes southeastern Alaska, the St. Elias region, and the Alaska Peninsula and adjacent islands, while under Copper River and Cook Inlet region are embraced the Kenai Peninsula and the Copper River and Susitna basins. The other geographical terms used in this table, Yukon basin and Seward Peninsula, need no definition.

Value of gold production of Alaska, with approximate distribution, 1880–1907.

Year.	Pacific coastal belt.	Copper River and Cook Inlet region.	Yukon basin.	Seward Peninsula.	Total.
1880	$20,000				$20,000
1881	40,000				40,000
1882	150,000				150,000
1883	300,000		$1,000		301,000
1884	200,000		1,000		201,000
1885	275,000		25,000		300,000
1886	416,000		30,000		446,000
1887	645,000		30,000		675,000
1888	815,000		35,000		850,000
1889	860,000		40,000		900,000
1890	712,000		50,000		762,000
1891	800,000		100,000		900,000
1892	970,000		110,000		1,080,000
1893	833,000		200,000		1,033,000
1894	882,000		400,000		1,282,000
1895	1,569,500	$50,000	700,000		2,328,500
1896	1,941,000	120,000	800,000		2,861,000
1897	1,799,500	175,000	450,000	$15,000	2,439,500
1898	1,892,000	150,000	400,000	75,000	2,517,000
1899	2,152,000	150,000	500,000	2,800,000	5,602,000
1900	2,606,000	160,000	650,000	4,750,000	8,166,000
1901	2,072,000	180,000	550,000	4,130,700	6,932,700
1902	2,546,600	375,000	800,000	4,561,800	8,283,400
1903	2,843,000	375,000	1,000,000	4,465,600	8,683,600
1904	3,195,800	500,000	1,300,000	4,164,600	9,160,400
1905	3,430,000	500,000	6,900,000	4,800,000	15,630,000
1906	3,454,794	332,000	10,750,000	7,500,000	22,036,794
1907	2,901,743	275,000	9,173,000	7,000,000	19,349,743
Total	40,311,937	3,342,000	34,964,000	44,262,700	122,935,237

Of this about $37,000,000 must be credited to the lode production, which is nearly all included in the Pacific coastal belt of the above table. Up to the close of 1907 there was only one productive auriferous lode mine in Seward Peninsula, and none either in the Yukon basin or in the Copper River and Cook Inlet region. The auriferous lode production, with the exception of that of the Apollo mine on Unga Island, southwestern Alaska, and a few small mines of the same general region, together with a small gold output from the copper deposits of Prince William Sound and from the auriferous lodes of Seward Peninsula, is all from southeastern Alaska. As the Treadwell group of mines has an output valued at $30,402,236, it will be seen that nearly five-sixths of the auriferous lode production is from this one ore body.

Accurate data regarding the source of the gold have been available only since 1906. They are summarized in the following table:

Source of gold in Alaska, 1906–1907, in values.

Kind of ore.	1906.	1907.
Placers	$18,607,000	$16,491,000
Siliceous ores	3,348,943	2,764,895
Copper ores	80,851	93,858

This table indicates that the placer production now overwhelmingly dominates in the total of gold output. This has, however, only been true since 1897, for previous to that time only about a third of the annual gold production was from the placers.

SUMMARY AND CONCLUSION.

It has been shown that gold is very widely distributed in Alaska, both in lodes and in placers; also that the production of the lode mines, outside of the Treadwell group, is insignificant. This does not mean, however, that the outlook for auriferous lode mining is not hopeful, for this is far from being the case. Up to the present time the cost of mining, except along a part of the Pacific seaboard, has been practically prohibitive for a lode-mining industry which is not based purely on the exploitation of bonanzas. Even along the seaboard there has been little systematic search for lodes. Most of the gold ores which have been found in the inland region have been of so low a grade as not to encourage their exploitation under present conditions of transportation. It will be clear, therefore, that there is no basis whatever for a quantitative statement of the gold reserves in the lodes of the Territory.

The known wide distribution of placer gold augurs well for future discoveries of this type of deposit. Most of the districts where mining operations are now going on have been so little prospected that little is known of their gold reserves. Some estimates, however, have been made for placer-gold reserves of the Yukon-Tanana region and Seward Peninsula. Those of the first province were made to include only the producing areas, while in Seward Pensinsula the bulk and value of the entire body of auriferous gravels was estimated. In the Yukon-Tanana region, which includes much the largest auriferous area, the gold contents of the producing part of the field are approximately valued at $100,000,000, not including the very large unprospected areas, while the auriferous gravels of the entire Seward Peninsula are estimated to contain about $300,000,000. It can not be too strongly emphasized that though all the data have been carefully compiled and the computations made with great care, yet there are so many unknown factors that the results are little more than guesses. No quantitative data of any kind are available for the other smaller districts, ten in number, but it is probably safe to estimate the gold in them as between $50,000,000 and $100,000,000. These values total about $500,000,000, which is the nearest approximation that can be given of the gold-placer reserves of the Territory. It is not impossible, however, that the Yukon-Tanana region alone may carry this amount of gold.

SILVER, LEAD, AND ZINC.

The silver production of Alaska has practically all been won incidentally to gold mining, and much the larger part of it has been recovered from the placer gold. There has also been a small recovery from the copper ores.

The total production of silver from 1880 to 1907, as nearly as can be determined, was 1,677,159 ounces, of which over three-quarters was from the placer gold. The following table shows the source of silver for the period that statistics have been available:

Source of silver from Alaska, 1906–7.

Kind of ore.	1906.	1907.
	Ounces.	*Ounces.*
Placers	76,835	40,847
Siliceous ores	15,772	14,653
Copper ores	18,577	34,357

There has been no lead production from Alaska, except a few tons recovered in the reduction of other ores. Galena is widely distributed, and some promising ore bodies have been prospected, but nothing is known of their extent. Such galena deposits occur in southeastern Alaska, on Prince William Sound, and in Seward Peninsula. Though attempts to exploit a galena ore body on Seward Peninsula date back to 1881 and have been continued intermittently to the present time and some small shipments have been made, this mine, called the Omalik, has never been on a commercial basis. The same statement applies to the mining of galena ores in other parts of the Territory.

Zinc blende has been found at a number of localities in Alaska, but the value of the ore bodies remains to be proved. No attempt has been made to mine zinc ores.

There are no data at hand on which to base any estimates of the reserves of the three metals here under consideration. With the increase of the gold output there will be a corresponding increase in the silver production.

COPPER.

DISTRIBUTION AND OCCURRENCE.

Copper ores are known to occur in commercial quantities on Prince of Wales Island (southeastern Alaska), Prince William Sound, and in the Chitina Valley of the Copper River district. They have also been found in a belt running from the Nabesna to the upper White River, in the Lake Iliamna region, and on the Seward and Kenai peninsulas. In these no ore bodies of proved commercial importance have been opened up, but the outlook for such in some localities appears hopeful.

On Prince of Wales Island, according to C. W. Wright, the copper ores, which are sulphides, occur along the contact of intrusives and limestones. U. S. Grant's description of the copper ores of Prince William Sound shows these to be sulphide ores which occur as lenses along shear zones. These shear zones are in greenstones or in contact zones between greenstones and graywackes. The Chitina belt, according to F. H. Moffit, includes both native and sulphide copper deposits. These occur at or close to a contact between a heavy greenstone (altered lava) and a limestone. This contact, along which mineralization seems fairly persistent though ore bodies of proved value have been exposed at only a few localities, has been traced for upward of a hundred miles.

The Nabesna-White River copper belt is of a similar character to that of the Chitina Valley, though here the value of the ore bodies found remains to be proved by further development work. In the Iliamna Lake region copper ores are said to be similar in occurrence to those of southeastern Alaska. Little is known of the other copper-bearing localities of the Territory.

STATISTICS.

Copper mining was first attempted on Prince of Wales Island in 1880, but the project was soon abandoned. The industry was begun again in 1900 in Prince William Sound, and five years later the Prince of Wales Island deposits also began producing. The total output of copper from Alaska up to the close of 1907 was 20,843,352 pounds, of which 12,368,975 pounds came from the Prince of Wales Island mines and the balance from Prince William Sound.

SUMMARY.

It is impossible to make any estimate of the tonnage of copper-ore reserves of the Territory. The developed ore bodies have been computed in a few mines by the operators, but even if these figures were available they would have little bearing on the problem of the ultimate reserves. Less than a score of copper mines have been opened up in Alaska, and all but one of these are located in two districts. In one promising district there has been only a little surface prospecting and this also holds true of the several widely distributed copper deposits which are not included in the four best-known districts. Even in the largest mines the workings in few cases extend to a depth of more than one or two hundred feet. It is evident, therefore, that the ore blocked out in the mines, whose copper content is probably less than 200,000,000 pounds of metal, has little bearing on the question of ultimate reserves, for it would not take into account either the undeveloped ore bodies already found or the possibilities of discoveries in the little-prospected fields. Moreover, any estimate of tonnage could include only the ores which can be mined at the present price of copper, while an increase of this price would make available lower-grade ores which can not now be commercially exploited. The problem is furthermore complicated by the irregularity of many of the copper deposits.

There can be no doubt that the output of copper from the Territory will increase during the next few years. The accessibility and cheapness of exploitation of the ores of the Pacific coast province invite copper-mining enterprises, in spite of the irregularity of occurrence of most of these deposits. A railway is now under construction up the Copper River valley which will not only lead to early shipments of a large amount of copper ores from the deposits already found, but will also stimulate further search and probably lead to the discovery of other ore bodies.

WATER RESOURCES.

INTRODUCTION.

The principal value of the water resources of Alaska is for generating power to be used for mining, now the only extensive industry. There are two general methods of utilizing the water power: (1) By converting it into electricity or other form of energy, for the purposes of lode and placer mining. By such means the power can be transmitted to the locality of use. This form of utilization is now almost entirely confined to the Pacific coastal belt of the Territory. (2) The more direct use of the water under head for sluicing, elevating, and hydraulicking the auriferous alluvium. This second form of utilization has been extensively practiced in small plants throughout the placer districts.

Many of the gold placers and lode deposits can be profitably exploited only by the utilization of water power. The water powers are also valuable to other industries, but up to the present time have not been so utilized, except in a small way for running electric-light plants, machine shops in some of the coastal towns, and some fish-product manufactories.

An adequate knowledge of the distribution, volume, and gradients of the surface water is, therefore, of first importance to the industry of the Territory. The underground waters of Alaska need not here be considered; none such have been developed and little is known about their occurrence. There is a possibility that in some of the placer districts there may be underground waters in sufficient quantity to justify their development for purposes of supplementing the inadequate surface waters. Artesian waters have in a few instances been found underneath the layer of perpetually frozen ground. These appear to be exceptional conditions, as usually the frost extends all the way to bed rock. Such ground waters, where they have been found, are probably very local in extent. There are also some potable waters derived from springs, but these, as well as the surface water used for towns, need not here be considered.

Facts regarding the water supply are scant and based almost entirely on the results of the investigations of the United States Geological Survey. These results are of two kinds—(1) the records of stream gaging, which furnish information as to the volumes of the watercourses, and (2) the topographic maps, which show the distribution of the water, as well as the gradients of the streams in which it flows. Measurements of stream flow have been carried on for three seasons (1906–1908) in some of the important placer districts of Seward Peninsula, for two seasons (1907–1908) in the Fairbanks district, and for one season (1908) in the Hot Springs, Rampart, and Birch Creek districts. These measurements furnish the only data on stream volume throughout the Territory, though a few corporations have obtained records from small areas preparatory to the installation of hydraulic plants.

The topographic data are more complete, for reconnaissance maps (scale 1:250,000, with 200-foot contours) of some 121,252 square miles have been made which cover most of the important mining districts and about 20 per cent of the entire area of Alaska. These reconnaissance maps furnish a general conception of drainage basins and stream gradients. In addition, 2,732 square miles have been mapped in detail (scale 1:62,500, with 25, 50, or 100 foot contours), yielding accurate information of the extent of drainage basins and of stream gradients.

Only two of the larger geographic provinces of Alaska will here be considered, namely, (1) the Pacific coastal region and (2) the central region, for, as far as can now be foreseen, it is only in these two that the water has any industrial value. These two provinces differ essentially in climate and relief and, indeed, present almost the extreme conditions as regards the occurrence and utilization of surface waters. In the coastal belt as a whole the topography is extremely rugged and many of the streams are fed by perennial snows, which, together with the large precipitation (75 to 120 inches), yield a large run-off with no great fluctuations during the summer months.

Beyond the coastal barrier the climate is semiarid (precipitation 10 to 20 inches), the relief is weak, and hence stream gradients are low, while there is no permanent snow. Another feature of the precipitation is that summer rainfall is very local. Moreover, the general frozen condition of the subsoil to bed rock probably prevents any considerable ground storage. These conditions make for a small run-off per square mile and very marked fluctuations in stream volumes. Moreover, the low relief makes it difficult to utilize the water under head.

Seward Peninsula, though not strictly a part of the central region, possesses the same general hydrographic conditions. The precipitation (10 to 30 inches), however, averages a little greater than in the Yukon basin. Here also the low stream gradients make much of the run-off unavailable for placer mining.

The conditions affecting surface waters in the area drained by Susitna and Copper rivers differ somewhat from those existing in the Pacific coastal region and in the inland province. In part this area has as strong relief as that along the seaboard, yet its precipitation is far less. On the whole, however, this region is better supplied with water than the Yukon basin.

PACIFIC COAST REGION.

In southeastern Alaska alone has there been any considerable utilization of water power. The Census Bureau collected the statistics of the developed water power in this part of the territory. Through the courtesy of the Director of the Census the following data are available. The statistics show that a total maximum of 15,699 horsepower has been developed and that 100 water wheels have been installed. Of this maximum 2,816 horsepower is available during low-water season. It is reported that at the localities where this power has been developed there is 14,135 horsepower available. Of the developed horsepower 3,403 horsepower is utilized by electric-light plants, canneries, and some other small industrial enterprises, and the rest by mining and smelting plants. The Treadwell group of mines alone utilizes some 6,647 horsepower. In addition to the above a few hunded horsepower is developed in other parts of the Pacific coast belt.

Southeastern Alaska affords conditions which are peculiarly favorable for the development of water power. The glaciation of this region has developed a topography which, with its cirques and many lakes lying at considerable altitude above sea level, is favorable to water storage. While the run-off during the summer months is much larger than during the winter, yet there are many localities where a large amount of power can be developed, even during the low-water stages.

YUKON BASIN.

There are no records which make it possible to state the quantity of water used for placer mining in the various Yukon districts, but it is known to be a large amount. Nor has stream gaging progressed far enough to determine the available water. However, it is probably safe to say that within a few years every supply so situated as to be directly applicable to placer mining will be utilized. Even when this has been brought about, the supply will be inadequate for the gold placers already opened up. In addition to this water directly applicable to placer mining, there are a number of water powers which can be utilized for certain mining operations by transformation to other forms of energy. It is probable that even after the development of these water powers the demands of future mining interests will not have been met. The utilization of coal to supply this demand is discussed elsewhere in this report. Mention should be made in this connection of the possibility of developing power along the streams which find their source in the high mountains stretching along the southern margin of the Yukon basin. These streams have not been measured and but few have been surveyed. They are known, however, to have a much larger volume than those of the central region proper, and the topography would appear to be favorable to water-power development. Some of the important placer districts lie within 50 or 100 miles of the mountain front.

The following table, which is based on the investigation of Mr. Covert, presents in summary form the available data regarding the run-off in the districts which have been investigated. It can not be too strongly emphasized that, as this is based on only one or two seasons' observations, the data presented are only an approximation.

Estimates of mean annual discharge and run-off of drainage basins in Yukon-Tanana region, Alaska.

[By C. C. Covert.]

District.	Year.	Second-foot per square mile.	Depth in inches.	Per cent estimated.[a]	Duration of record.

SEWARD PENINSULA.

What has been said of the Yukon basin applies also to Seward Peninsula. Here, too, nearly all the water available for direct application to placer mining will soon be utilized, and even then can not meet the demand. Some important undeveloped water powers are known to exist in this province.

The topography of Seward Peninsula, like that of the Yukon basin, is of low relief, and therefore a comparatively small part of the run-off can be made available for mining. In the mountain mass, including the Bendeleben and Kigluaik ranges, the conditions for water storage are somewhat more favorable than in other parts of the peninsula. Here there are some glacial cirques, and though these are of comparatively small extent, they have an influence in the conservation of water and snow. What is of still greater importance, however, is the greater rainfall which occurs in these high mountains compared with other parts of the peninsula.

Mr. Henshaw has summarized his three seasons' observations on stream flow in Seward Peninsula in the table which follows. The value of the data contained in this table will be increased by considering the character of the topography of the basins whose run-off is given. Kruzgamepa River, at Salmon Lake, drains a basin typical of the Kigluaik and Bendeleben mountain areas. Kuzitrin River and Imuruk Lake lie in the northern portion of the peninsula and represent the area north of the mountains. There are not sufficient data to make any estimate of the yearly run-off from the country south of the mountains.

Estimates of mean annual discharge and run-off of drainage basins in Seward Peninsula, Alaska.

[By F. F. Henshaw.]

The discharge of Kruzgamepa River at Salmon Lake has been assumed to decrease regularly from October 1 to a minimum of 30 second-feet on April 20, then to increase slowly until the break-up of the ice, and more rapidly until the date of the beginning of records, which has been taken as the maximum for the year. The run-off from snow for 1908 was taken as 70 per cent of the mean of that for the two previous years.

The run-off of Kuzitrin River for May, 1908, was taken as 75 per cent of that for June, and for the remainder of the year as 0.06 second-feet per square mile. The run-off for 1907 was estimated by comparison with the two years' record at Imuruk Lake. The flow into Imuruk Lake was determined by closing the dam at the outlet and noting the rise of the water surface.

WASTE OF STRUCTURAL MATERIALS FROM FIRE AND OTHER CAUSES.

By Herbert M. Wilson,
United States Geological Survey.

The mineral structural materials may be divided into two classes:

(*a*) Iron, steel, copper, and other metallurgical products, the supplies of which are limited and which are themselves subject to destruction through weathering, fire, etc., and

(*b*) Stone, clay products, and cement and concrete manufactures, which are less subject to destructive agencies and the supplies of which are practically inexhaustible.

The substitution of the latter materials for the more commonly used wood and metal manufactures should be encouraged as having an important influence on the preservation of the supplies of the more perishable and less abundant materials. The use of building stone, clay, and cement products in this country has been restricted by competition with the much cheaper wood products and the more easily fabricated and more available metal products. Improved methods of preparing the raw materials for use in building construction are rapidly reducing this difference in cost, and careful investigation both as to the physical properties and the more suitable structural forms should have an important influence on further reducing this difference in cost and the enlargement of the use of the more permanent and less perishable materials.

The value of the cement manufactures has increased from $9,859,000 to $55,803,000 within the last decade, or nearly sixfold. The value of the clay products has increased in the same time from $74,487,000 to $185,942,000, or over double, while the building stone has in the same period increased in value from $28,635,000 to $71,106,000, or nearly three times. As the Government, through its investigations, is determining the strength, durability, and fire-resisting properties and the more suitable forms of these materials and disseminating information relative to the comparative cheapness and greater permanence of such materials, a still greater relative increase in their use may be confidently looked for in the near future.

Within the past few years marvelous strides have been made in the substitution of iron and steel for wood, owing to the careful investigations into their properties made by engineers, physicists, and chemists and the great amount of attention given their fabrication by manufacturers and architects. More recently the engineering and technical professions have advanced to a great extent the uses of cement and concrete manufactures; but in a vastly greater period of time practically nothing has been done toward ascertaining the physical and chemical properties and better mode of manufacture and use of the products of clay and stone. Undoubtedly great progress in the substitution of all of these materials for metal and wood in building construction may now reasonably be looked for, with proper encouragement from the Government as an exemplar in the methods of testing and assembling such materials.

WASTE OF STRUCTURAL MATERIALS.

The waste of natural mineral resources used in building and engineering construction is of three kinds:

(1) That due to improper and wasteful methods of mining and preparing for market.

(2) That due to excessive use in structural forms, because of ignorance of the strength, durability, etc., of the materials used.

(3) That due to destruction by fire on account of the inflammable character of building construction, inadequate building laws, and the nonenforcement thereof.

The waste of raw mineral products due to improper methods of mining and shipping is fully discussed elsewhere in this report. There is an equally large waste of these materials due to uneconomical and inefficient methods of manufacture, including waste of the fuel, as in the preparation of coke used in refinement of iron ores and of fuel used in burning cement, clay products, etc. Not until a better knowledge is had as to the appropriate structural material, be it steel, iron, stone, cement manufactures, or clay products for any particular purpose, will it be possible to reduce a portion of this wasteful consumption.

Most of the information available concerning the strength and suitability of such materials has been procured by individuals, based on insufficient data and tests. The Government, as the largest consumer of such materials, should, as a matter of economy, conduct exhaustive tests of the kinds which have proven so successful under the Forest Service in developing the most suitable woods for each particular use. These tests should be conducted with a view to establishing the physical properties of these materials and to suggesting improved methods of manufacture which may prove not only economical, but shall improve the quality of the materials in use and extend their life. These investigations should include the assembling of information relative to the most fire-resisting and fireproof forms of construction, the former having in view the prevention of conflagrations due to secondary or exposure fires, and the latter the prevention of the destruction of the building in which the fire may originate. They should also include extended investigations with a view to preventing the loss of structural materials exposed to the action of salt water, the action of alkalies in the arid regions, and to similar destructive agencies.

A great many structural materials are used in excessive quantities in the erection of buildings and engineering works, while materials of superior quality may be little used because of lack of information as to their properties. The average architect, engineer, or contractor does not take chances of using unfamiliar materials or designs, but confines himself to those he has knowledge of as having proven moderately successful. Authoritative investigations should be made of such materials with a view to establishing the strength and properties of each under varying conditions, and of pointing out the most economical material for each use. The present systems of building construction are expensive and wasteful, because of lack of exact knowledge as to the strength of the materials when fabricated into various forms of construction.

The investigations so far conducted by the Geological Survey indicate the local availability of gravel, sand, or broken stone suitable for making concrete or reenforced concrete structures, where it had been previously assumed that such materials were not suitable and the charge for haulage from distant quarries often rendered the cost of such construction excessive. A better knowledge of the distribution of these constituent materials of concrete, and of the building stones and clays locally available, will encourage the use of these durable structural materials in competition with forest products and other less permanent materials, thus conserving the latter.

The use of excessive quantities of structural materials, due to ignorance as to their strength, results from the very incomplete tests regarding such strength, in the absence of which conservative designers use an unnecessarily large factor of safety. Engineers and architects adopt working stresses for metal and reenforced concrete of from one-fourth to as high as one-eighth the supposed working strength of the material, which may mean that from three to six times the amount of material that is necessary is being used. But lighter designs can not safely be adopted until absolute knowledge is had, through long series of tests and investigations, which will thoroughly establish the strength and durability of each structural material for the specific purpose for which it is to be used.

As shown elsewhere in this report, the iron resources of the world, and those of the United States in particular, are not limitless. According to the present ratio of increase in consumption of iron and steel products, the supply of these materials in the United States will be exhausted in a few centuries. The forest products of the United States are rapidly approaching exhaustion, and unless immediate means be taken to limit their waste and reproduce their growth, a fraction of a century will see their exhaustion. Under the circumstances, we must turn to concrete-making materials, such as cement, sand, and gravel, to the raw clay from which brick and tile are manufactured, and to building stones, the amounts of all of which in the United States are practically unlimited, as substitutes for the above more perishable materials.

FIRE LOSSES.

The greatest source of waste of structural materials and of money values in the United States is that due to fires and this is one which from the example set in European countries can, as hereafter shown, be most greatly reduced by the substitution of fire-resisting building materials for the inflammable construction now so prevalent.

The cost of fire to the country, including not only property destroyed, but maintenance of fire departments, payment of insurance premiums (less benefits returned), protective agencies, additional cost of city water supplies to meet fire drafts, etc., amounted to over $456,-

485,900 in 1907. This fire tax exceeded the total value of the gold, silver, copper, and petroleum production of the United States in 1907 and was thirteen times the interest on the national debt. The property loss from fires in the United States in 1907 was $2.51 per capita. The total per capita loss, including interest and maintenance charges on fire departments, excessive water supplies, insurance premiums, etc., was $5.34.

In addition, 1,449 persons lost their lives in fires during the year 1907, while 5,654 were injured. The loss of life during 1908 was even greater, on account of the Boyertown (Pa.) opera-house fire and the Collingwood (Ohio) school disaster. Undoubtedly the greater part of this immense waste in material, money values, and lives could be prevented by the use of suitable structural materials and the better fabrication of these into building construction. Such construction would cost little more than the present combustible building, and would result in real economy in the long run, and in the extension of the life of the mineral and forest resources.

Possible means of reducing this enormous waste due to fire and conflagration are:

(1) By tests and investigations to determine the relative fire-resistive properties of building materials, the relative rates of heat conductivity of such materials, and the developments of systems of construction which offer the maximum resistance to fire. These tests should have in view the classification in order of merit of the building materials and the cheapening of cost of construction by the use of those best suited to the purpose, since materials actually cheaper are often not employed through lack of knowledge of their available properties.

(2) By the dissemination of information regarding the less inflammable materials of construction, their strength and durability, the methods of utilizing them in building construction, and the availability of the most suitable of these materials near the locality in which they are wanted.

(3) By the enactment of building codes and the enforcement of the same with a view to securing more fire-resistant and more fireproof construction. In European cities the erection of wooden buildings is prohibited, and the official supervision of brick, stone, steel, and cement construction is such as to diminish danger from fire due to defective flues, poor electric wiring, etc., and as to confine the fire to the building in which it originates.

The fire waste in the United States for the year 1907 reached the enormous total of $456,485,900, exclusive of forest, mine, and marine fires. Of this total $109,156,894 was due to the destruction of buildings and $105,927,815 to the loss or injury of contents. A noteworthy fact is that of this loss 27 per cent was due to exposure, i. e., the fire extended beyond the building of origin. This loss is quite evenly distributed between urban and rural districts; the loss in cities amounting to $107,093,283, and in villages and the country $107,991,426, and as the urban and rural population are almost exactly equal the per capita loss in each division is very evenly divided. Only $68,000,000 of this loss was on brick, iron, stone, and other slow-burning constructions, while over double this amount, or $146,000,000, was on frame buildings. In the last thirty-three years the total fire waste, being the value of property destroyed, amounted to over $4,484,000,000, while the total cost of such fires doubtless aggregated double this vast sum.

Even where frame buildings are permitted or are now in existence, the loss might be greatly reduced by more careful oversight over defective flues, wiring, etc.

The cost of insurance amounted to $145,604,344, being the difference between the total premiums paid on policies, $259,768,813, and the benefits paid to the insured, $114,164,469. The cost of fire-department maintenance and interest on capitalization amounted to $44,237,100 of the total. The interest on the capital cost of fire-protective devices, such as automatic sprinklers, fire extinguishers, etc., and the annual cost of private watchmen's service, etc., amounted to about $18,000,000. The total for the year 1907 is swelled by the amount invested in city water-supply service and distributing systems primarily necessary for fire protection and over and above that estimated as necessary for domestic consumption. This includes interest on the capital invested in city fire protection, $9,826,800, and maintenance charges, $8,465,500, the sum of which aggregates about 22 per cent of the total cost of water supply. The depreciation charges and taxes on all the above amounted to $15,167,500.

A large portion, probably over one-half of the insurance, one-fourth of the city water-supply and distribution charges, one-half of the fire-department charges and three-fourths of the fire losses, or a total of $234,196,956 per annum, may be reasonably expected to be saved, when through the dissemination of information relative to less inflammable structural materials and the enactment of better building codes, building construction in the United States shall become of a kind similar or superior to that now found in European countries.

HOW THE STATISTICS WERE GATHERED.

The details making up the above summary of fire losses of structural materials and property values, as well as the invested capital, are submitted in the following tables and discussion, chiefly the work of John L. Cochrane, statistician, assisted by Frank D. Brown:

At the request of the National Conservation Commission, the United States Geological Survey, through its technologic branch, took up the task of gathering the statistics of fire losses of the country. Requests for the official records of fire loss were sent to the chiefs of fire departments in 5,175 incorporated places in the United States (all places of 1,000 population and upward) with the result that 1,000 replies were received. Four thousand second requests were sent out, and to these 1,796 fire chiefs responded, making a total of 2,796 cities and villages heard from out of 5,175.

These cities and villages, with a population aggregating 34,102,453 reported a fire loss of $86,476,029, or a per capita loss of $2.54.

It was with the greatest difficulty that figures were obtained showing separately the losses on frame and brick buildings, on buildings and contents, and losses on buildings in which fire did not originate, since many of the fire chiefs merely sent an estimate of the total loss. After much correspondence, 2,300 out of the 2,796 chiefs who replied originally gave the detailed figures.

In order to obtain a correct estimate of the losses in the rural districts, 5,000 blanks were sent to postmasters located in counties that were strictly rural, the aim being to exclude all counties that contained villages of any sizes whatever. The blanks were apportioned among the various States according to their percentage of rural population, the States with a large farming population getting more than the States whose population centered mainly in the cities. Responses were received from 1,898 postmasters representing a population of 1,410,383. These postmasters reported a total loss of $3,519,769, which gives a per capita loss of $2.49.

Thus it will be seen that reports were received from 4,694 cities, villages, and rural communities with a total population of 35,512,836 and a total loss of $89,995,798, a per capita loss for the entire United States of $2.51, or an aggregate loss for the United States of $215,084,709.

The only statistics with which these are comparable have been gathered by the National Board of Fire Underwriters. This organization, composed of the leading fire underwriters of the country, has given out estimates of the fire losses for several years, in the hope of showing the public how much of the loss is preventable and with a view toward creating a public sentiment in favor of better building construction.

In order to ascertain the additional cost imposed upon the country by fires over and above that represented by simple fire waste or destruction of property and the cost of public fire-fighting departments and systems and insurance losses above referred to, careful statistical inquiry was made into the additional cost of construction and maintenance of city water supplies necessary on behalf of protection against conflagration over and above cost pertaining to domestic supply, street sprinkling, and the incidental fire service necessary to restricting a fire within the building of origin. Information was also procured regarding the cost of private fire-protective measures such as automatic fire sprinklers, fire extinguishers, and grenades, private watchmen's services, etc., imposed by the risks due to inflammable construction. Finally, an attempt was made to ascertain the losses to the country from marine fires and disasters. The statistics regarding public water supplies were secured by correspondence and the submission of questions to the superintendents of water supply in every city in the United States and to the more prominent hydraulic engineers. In all, 5,700 blank report forms were sent out to which 1,500 replies were received, of which, however, but a small percentage was complete enough for tabulation. The total cost in each case was obtained from the census reports for cities of above 30,000 population owning waterworks and the remainder from the Spectator.

This total cost of waterworks systems in the United States was segregated to show the total cost in each of the five geographical divisions of the United States, viz: The Middle Atlantic and New England States; the Southern and Southeastern States; the Central States; the Rocky Mountain or arid region; and the Pacific Slope States.

The total cost of the waterworks systems in each of the geographical divisions was then subdivided to show the total cost in cities according to the following classification: Population of 100,000 or over; population of 30,000 to 100,000; population of 5,000 to 30,000; and population under 5,000.

This same plan of classification was pursued in tabulating the reports received from engineers and superintendents who gave in detail the information sought. This detailed information for each geographical division and classification by size of cities was then applied to the total cost of waterworks systems for the corresponding geographical divisions and classifications by size of cities, and the same proportionate distribution made for the various inquiries.

The procurement of data of losses from marine disasters was even more difficult than the above. This was arrived at by securing the total paid by American companies and the total paid by foreign companies doing United States business, giving an aggregate total for the year 1907 of $11,621,827. It is not evident that a portion of this may not include some Canadian insurance or cover some duplication. Endeavors to secure data on cost of private fire protection were even less successful. Information received from the manufacturers of automatic sprinklers, fire extinguishers, etc., and estimates of the cost of private watch service derived from special investigations in a number of prominent cases lead to the belief that the invested capital, including construction, equipment, etc., aggregates about $50,000,000, while interest upon this amount and the cost of watchmen's services, etc., would amount to an annual charge of about $18,000,000.

FIRE WASTE.

The total loss from fire in the United States during 1907, $215,084,709, represents a waste of nearly $600,000 for every day of the year, or $25,000 for every hour of the day. The term "waste" is used because the fire loss is one that is absolutely irretrievable, and constitutes a tremendous drain upon the natural resources of the country. The insurance on a burned building does not bring back the property that was destroyed—it simply equalizes the loss between all others whose property is insured—and the money paid by the insurance companies does not by any means cover the total losses sustained. Underwriters declare that from 75 to 80 per cent of all property is insured, but two State fire marshals disagree with this statement after tabulating the fire losses for their States. The State fire marshal of Ohio, D. S. Creamer, finds that but 52 per cent of the property is covered by insurance. This statement seems to be borne out by the annual report of the National Board of Fire Underwriters for 1907, which gives as the total losses paid by all companies during the year $114,164,469.

The fire waste for the last thirty-three years, according to the National Board of Fire Underwriters, reached the tremendous total of $4,484,326,831.

Fearful as it is to contemplate this great destruction of the natural resources of this country, the situation becomes more appalling when it is realized that this waste is rapidly increasing. The National Board of Fire Underwriters gives the following estimates of the fire waste for the last thirty-three years:

Annual fire losses in the United States for thirty-three years, 1875–1907.

[Compiled by the National Board of Fire Underwriters.]

Years.	Aggregate property loss.	Years.	Aggregate property loss.	Years.	Aggregate property loss.
1875	$78,102,285	1886	$104,924,750	1897	$116,354,575
1876	64,630,600	1887	120,283,055	1898	130,593,905
1877	68,265,800	1888	110,885,665	1899	153,597,830

ANALYSIS OF LOSSES IN THE UNITED STATES.

The following table of the fire losses in the United States in 1907 gives a number of interesting comparisons of the total losses sustained in the cities and in the rural districts:

Fire losses in the United States for 1907.

[Statistics gathered by the United States Geological Survey.]

	Total.	Urban.	Rural.
Fire loss:			
Buildings	$108,156,894	$50,173,625	$58,983,269
Contents	106,927,815	56,919,658	49,008,157
Total	215,084,709	107,093,283	107,991,426
Brick, etc.:			
Buildings	31,092,687	19,816,474	11,276,213
Contents	37,332,580	29,092,270	8,240,310
Total brick, etc	68,425,267	48,908,744	19,516,523
Frame:			
Buildings	78,064,207	30,357,151	47,707,056
Contents	68,595,235	27,827,388	40,767,847
Total frame fire loss	146,659,442	58,184,539	88,474,903
Number of fires:			
In brick, etc., buildings	36,140	25,297	10,843
In frame buildings	129,117	80,109	49,008
Total number of fires	165,257	105,406	59,851
Loss per capita, United States	2.51	2.54	2.49

It will be seen that the loss is rather evenly divided between the urban and the rural population, the total loss in the cities and villages amounting to $107,093,283, and in the rural districts to $107,991,426. The total urban population is estimated at 42,160,710, and the rural at 43,162,051. The big losses in the cities and villages are not surprising, for in these are located many large buildings filled with millions of dollars worth of property; buildings which are subjected to additional risk because they adjoin one another or are near each other. In the rural districts the buildings are widely separated and contain property that does not compare in value with that in the cities, yet the losses are as great in these districts. The only conclusion that can be drawn from this condition is that the remarkable efficiency of the fire departments of the cities prevents a loss much greater than occurs, and that the absence of fire-fighting apparatus in the rural districts permits the loss in fires to be total.

This fact is plainly shown in the total building loss of the country, the fire departments keeping the loss in cities and villages down to $50,173,625, while fires in the rural districts consumed buildings valued at $58,983,269.

The contents loss in the cities and villages was $56,919,658, as against $49,008,157 in the rural districts; which again proves the contention, in spite of the great loss in the rural districts, as it is well known that the value of the property in city buildings is many times greater than that in buildings in rural communities.

The losses on brick, stone, and steel buildings in cities and villages amounted to $19,816,474, and on contents, $29,092,270; in the rural districts the losses on these buildings were $11,276,213, and on the contents, $8,240,310. The much heavier losses in the cities and villages on the brick, stone, and steel buildings are undoubtedly due to the few buildings of this character in the rural districts in comparison to the number in the cities.

The losses on frame buildings in the cities and villages amounted to $30,357,151, and on the contents to $27,827,388. In the farming communities the losses on these buildings reached a total of $47,707,056, and on the contents $40,767,847. This once more tells of the efficiency of the fire departments in coping with the flames in cities and villages and the utter lack of fire protection in the rural districts.

CAUSE OF FIRE WASTE IN THE UNITED STATES.

The great fire waste in the United States is undoubtedly due to the predominance of frame buildings. In most European cities frame buildings are positively prohibited within the limits of the municipalities, and but few are erected in the rural districts, owing to the scarcity and high price of lumber. In the United States the conditions have been exactly reversed. Lumber, at least until recently, has been the cheaper material, besides being more easily worked than brick, stone, and steel. The result has been that a great majority of the homes of the country and many factory buildings, warehouses, etc., have been made out of lumber.

Of the total losses sustained in the United States in 1907, more than two-thirds were on frame buildings. The exact losses are, $146,659,442 in frame buildings and $68,425,267 in brick, stone, and steel buildings, as shown by the foregoing table.

Another illustration of the influence of frame buildings upon the fire loss of the country is suggested by grouping eleven States which are practically treeless and comparing them with eleven States in which there is still an abundance of timber, the argument being that there will be a greater proportion of frame buildings in the States where lumber is plentiful because of its cheaper price. The States in which there is a supply of lumber show an increased per capita of loss of 59 cents over the per capita of the treeless States, as seen by the following table:

The per capita fire loss for 1907 in 11 States where timber is scarce and in 11 States where timber is plentiful.

[Statistics gathered by United States Geological Survey.]

	Total population.	Total fire loss.	Per capita.
Group 1.—States having scarcity of timber:			
Iowa, Illinois, Oklahoma, Connecticut, Delaware, New Jersey, South Dakota, Rhode Island, Kansas, Nebraska, and North Dakota	16,785,460	$38,006,558	$2.30
Group 2.—Showing timbered States:			
Washington, Louisiana, Texas, Mississippi, Wisconsin, Arkansas, Michigan, Pennsylvania, Minnesota, Oregon, and North Carolina	25,560,533	73,895,950	2.89

A study of the fire losses of the United States from the standpoint of geographical division of the States—a division frequently used by the Census Bureau—gives interesting results. The remarkable feature is the per capita loss in the South Central States—Kentucky, Tennessee, Alabama, Mississippi, Louisiana, Texas, Oklahoma, and Arkansas, $3.66—more than $1 in excess of the per capita of any of the other divisions. All of the States in this division have much timber; therefore, many frame buildings. These States also have the handcap of inefficient fire protection compared with the States of the North and East. The total and per capita losses according to geographical divisions of the States are as follows:

The per capita fire losses for 1907 in the United States as shown by geographical divisions of the States.

[Statistics gathered by U. S. Geological Survey.]

Geographical division.	Total population.	Total fire loss.	Fire loss per capita.
North Atlantic:			
Maine, New Hampshire, Vermont, Massachusetts, Rhode Island, Connecticut, New York, New Jersey, and Pennsylvania	23,779,013	$59,447,532	$2.50
South Atlantic:			
Delaware, Maryland, District of Columbia, Virginia, West Virginia, North Carolina, South Carolina, Georgia, and Florida	11,574,988	25,349,223	2.19
North Central:			
Ohio, Indiana, Illinois, Michigan, Wisconsin, Minnesota, Iowa, Missouri, North Dakota, South Dakota, Nebraska, and Kansas	29,026,645	68,793,148	2.37
South Central:			
Kentucky, Tennessee, Alabama, Mississippi, Louisiana, Texas, Oklahoma, and Arkansas	16,368,558	59,908,922	3.66
Western:			
Montana, Wyoming, Colorado, New Mexico, Arizona, Utah, Nevada, Washington, Oregon, and California	4,783,557	12,676,426	2.65

While the prevailing material of construction—lumber—is largely responsible for the great fire waste of the United States, there is a cause lying back of all of this—faulty construction and equipment of buildings. The list of causes of fires is headed by defective chimneys, flues, fireplaces, and heating and lighting apparatus, all of them faults of construction and equipment. Matches, sparks, and explosions figure prominently in the list, followed by incendiarism, electricity, and lightning. Nearly one-fourth of the fires are labeled "unknown cause," which indicates forcibly the listless attitude toward this waste, not only of the general public, but also of the men directly charged with protecting property against fire—the officials of municipalities and others.

FIRE WASTE IN EUROPEAN CITIES.

In 1905 the Bureau of Manufactures of the Department of Commerce and Labor sent letters of instruction to all the principal United States consular officers in Europe requesting information concerning the fire losses of European cities; also a statement regarding the fire insurance practice in those cities. Unfortunately the statistics gathered were not all for the same year, some cities reporting for 1901, others for 1903, and still others for 1904, a few failing to make any report. It is claimed, however, that there is but little variation from year to year in the fire losses of European cities, and for this reason the figures were tabulated.

Cities of Austria, Belgium, France, Germany, Norway, Russia, Switzerland, and the United Kingdom, with a reporting population of 19,913,916, had a loss of but $9,582,340, a per capita of 48 cents. Russia had the highest loss, $3,100,823, in a population of 2,673,427, a per capita loss of $1.16.

If the United States had Europe's per capita of 48 cents, in a total population estimated by the Census Bureau for 1907 as 85,532,761, the total fire waste in this country for the year would amount to $41,055,725, a saving of natural resources to the extent of $174,028,984.

Taking the maximum per capita in Europe, $1.16 in Russia, and the fire waste in the United States would amount to $99,218,002, or $116,314,759 less than it did.

The principal reason for the great difference between the amount of fire waste in the United States and Europe is that there are but few frame buildings in Europe and practically none in the great cities.

Consul Hossfeld, of Trieste, Austria-Hungary, in his official report to the State Department on the fire losses in the city he represents, said:

> The laws of Trieste and its territory prohibits the construction of wooden buildings. Only sheds and buildings of a temporary nature may be constructed of wood, such as are intended to serve as a shelter for workmen or for the storage of materials while permanent buildings are being constructed.

Consul Harold S. Van Buren, of Nice, France, wrote:

> There may be a few sheds of wood or detached stables of a temporary character, but not sufficient to form a portion of the statistics.

Consul John C. Covert, of Lyons, stated:

> An official in the office of the mayor informed me that there are no wooden buildings in the city, except a few old sheds, constructed without permission and permitted to remain, as they are in open fields and of no danger, being some distance from other buildings.

Consul-General Frank H. Mason wrote concerning Berlin, Germany:

> The comparative immunity of Berlin from disastrous fires, results not from the efficiency of its fire department—although it does promptly and well what

work it has to do—but from the absence of wooden houses and the solid, careful construction of all kinds of stone and brick buildings under the rigid scrutiny of the building police.

The following statement is made in Special Consular Reports, volume 38, Bureau of Manufactures, Department of Commerce and Labor, in discussing the insurance in foreign countries:

> In Europe the fire insurance laws are remarkable, chiefly because they compel insurance in some countries, while in all cities they prevent great losses by insisting on the erection of only stone and brick buildings. The fire-department systems are ridiculously inadequate as compared with those of American cities, yet the net results are better. French law compels insurance against fire not only for the benefit of the owner, but for his neighbors. In Germany building insurance is compulsory and in some kingdoms it is a government monopoly. Russia has an elaborate system of central and local government insurance and compels all buildings to be insured. By a law recently enacted the Swiss method of insuring against the loss of time by fire has been made almost impossible. In some of the cantons insurance against loss by fire is compulsory.

The countries of Europe with their reporting city populations and fire losses are as follows:

Fire losses in cities of Europe.

[Statistics gathered by the Bureau of Manufactures.]

Country.	Population.	Fire loss.	Per capita.
Austria [a]	193,387	$72,355	$0.37
Russia [a]	2,673,427	3,100,823	1.16
United Kingdom [a]	4,319,816	1,795,750	.42
Belgium [b]	312,987	178,766	.57
Germany [b]	7,446,447	1,832,402	.25
Norway [c]	222,373	207,000	.93
Switzerland [c]	715,712	192,500	.27
France [d]	4,029,116	2,202,744	.55
Total	19,913,265	9,582,340	.48

[a] Losses for 1904.
[b] Some cities of country report for 1903; others for 1904.
[c] Losses for 1903.
[d] France reports for 1904 with exception of city of Lyon which is for 1901.

Sometime after these statistics were prepared the National Board of Fire Underwriters obtained permission from the State Department to send their own queries to the consular officers in Europe, with the result that figures showing the fire losses in six countries were obtained, some of them for a period of several years. These figures showed the surprisingly low per capita of 33 cents for the six countries, and are as follows:

Fire losses in six European countries.

[Statistics gathered by the National Board of Fire Underwriters.]

Country.	Years.	Fire loss, annual average.	Population 1901.	Loss per capita.
Austria	1898-1902	$7,601,389	26,150,507	$0.29
Denmark	1901	660,924	2,568,919	.26
France	1900-1904	11,609,275	38,595,500	.30
Germany	1902	27,655,600	56,367,178	.49
Italy	1901-1904	4,112,725	32,449,754	.12
Switzerland	1901-1905	999,364	3,325,023	.30

Or an average loss per capita of $0.33.

EUROPEAN AND AMERICAN LOSSES COMPARED.

Another comparison, which is perhaps even more interesting as illustrating America's needless waste and Europe's prudence, is given in the following table of per capita loss in cities of the United States and Europe, arranged in classes according to their populations:

Per capita fire losses in American and European cities, classified according to population.

[Statistics for the United States gathered by the Geological Survey, and for Europe by the Bureau of Manufactures.]

	Per capita loss, United States, 1907.	Per capita loss, Europe.
Cities over—		
300,000	$2.24	$0.65
100,000 to 300,000	2.14	.37
50,000 to 100,000	2.47	1.67
30,000 to 50,000	3.28	.72
10,000 to 30,000	2.37	.81
Under 10,000	3.47	....

FIRE LOSSES IN CITIES OF EUROPE AND AMERICA OF EQUAL SIZE.

Comparing American and European cities of the same size, and the following per capita losses are found:

Fire losses in American and European cities of the same size.

[Statistics gathered by U. S. Geological Survey and Bureau of Manufactures.]

European losses for 1904.				United States losses for 1907.			
	Population.	Fire loss.	Per capita.		Population.	Fire loss.	Per capita.
Paris, France	2,714,068	$1,266,282	$0.47	Chicago, Ill	2,049,185	$3,937,105	$1.92
Frankfort, Germany	324,500	99,492	.31	Cincinnati, Ohio	345,230	1,971,217	5.70
St. Petersburg, Russia	1,500,000	2,128,541	1.42	Philadelphia, Pa	1,441,735	2,093,522	1.45
Birmingham, England	550,000	226,506	.41	Baltimore, Md	553,669	916,603	1.66
Sheffield, England	426,686	75,989	.18	Cleveland, Ohio	460,000	515,194	1.12
Toulon, France	101,602	55,391	.55	Atlanta, Ga	104,984	225,237	2.15

Molenbeek, Belgium	63,678	106,150	1.67	Evansville, Ind	63,957	196,702	3.08
Laiken, Belgium	31,121	22,349	.72	Oshkosh, Wis	31,033	80,500	2.59
Etterbeck, Belgium	23,992	19,504	.81	Easton, Pa	25,238	32,073	1.27

CONFLAGRATIONS.

Since the year 1866 the conflagration losses in the United States have totaled the sum of $936,551,135, according to the tabulation made by the National Board of Fire Underwriters. By conflagration is meant all fire involving a loss of half a million dollars and over.

The conflagrations of 1907 cost the United States $18,475,000, according to the same authority.

The year 1908 promises to exceed the conflagration loss of the preceding year, one conflagration alone, that at Chelsea, Mass., on April 12 and 13, involving an insurance loss of $8,846,879, as reported by the underwriting companies to the Massachusetts insurance commissioner.

The notable conflagrations of the United States were those at Chicago, in 1871; Boston, 1872; Baltimore, 1904; and San Francisco on April 18, 1906. The earthquake and fire at San Francisco resulted in a total property loss of $350,000,000, exceeding in amount any previous similar disaster in the history of the world.

The fact that no other country suffers such enormous conflagration losses has led to a general investigation of the causes by fire underwriters, fire marshals, officials of States and municipalities, and students of economic conditions, and the conclusion has been that poor and defective construction of buildings and equipment are responsible. The investigation has further disclosed that an increase in the number and severity of conflagrations may be expected until there is a decided improvement in the methods of construction.

The danger of conflagration is present in every city and village of the United States, and with it the possibility of large loss of life. The most efficient fire department in the country is powerless when once a fire gets considerable headway in a locality where bad construction prevails.

The Ohio fire marshal, in his annual report for 1907, in urging new building codes for Cleveland and Cincinnati, the two largest cities of the State, says: "Either city may at any time suffer a conflagration costing $300,000,000."

The October, 1908, Quarterly of the National Fire Protective Association, on the subject of better buildings, says:

> The average American city is full of fire traps. Buildings of great area, without fire cut-offs, with large floor openings, with unprotected windows, and with very combustible contents are too numerous to prove the exception to any rule. These are conflagration breeders. Fire travels through these buildings rapidly and under certain conditions can get beyond even the best fire department, and sweeping through the unprotected windows of surrounding buildings will soon cause a conflagration.

LIVES LOST IN FIRES.

During the year 1907 fires caused the death of 1,449 persons and the injury of 5,654, according to the information gathered by the United States Geological Survey. These figures are incomplete and perhaps do not represent more than half the persons who were victims of fires. Many fire chiefs of large cities failed to report any deaths, because such were not properly included in their annual reports. The cause of this again is faulty construction in buildings—in many instances lack of appreciation on the part of cities of the responsibility to safeguard the lives of their citizens or ignorance of what is demanded to protect against fires.

The Iroquois fire in Chicago, December 30, 1903, in which 600 persons lost their lives, was a terrible object lesson in bad construction and equipment, yet this was not sufficient to stop these disasters. January 13, 1908, fire in an opera house at Boyertown, Pa., cost the lives of nearly 200 women and children. Two months later, March 4, 165 children were burned to death in a schoolhouse at Collinwood, Ohio. With proper construction of buildings none of these lives would have been lost.

SUMMARY.

The capital investment and the annual maintenance cost making up loss and expense on account of fire losses, fire protection, cost of waterworks chargeable to conflagration service, maintenance of fire departments and private fire-fighting devices are summarized in the following table.

Capital invested for fire protection and annual loss and expense on account of fire (United States, 1907.)

Annual loss and expense:		
Total fire loss		$215,084,709
Fire protection—		
Amount of fire-insurance premiums paid above amount of losses paid		[a] 145,604,362
Total annual expense of waterworks chargeable to fire service—		
Depreciation and taxes	4,603,731	
Interest charge	[b] 9,826,867	
Maintenance	8,465,487	
		28,856,235
Total annual expense of fire departments—		
Depreciation and taxes	4,603,731	
Interest charge	[c] 4,282,540	
Maintenance	40,054,574	
		48,940,845
Total annual private fire protection		18,000,000
Total annual loss and expense		456,486,151
Investment in construction and equipment:		
Total cost of waterworks (construction and equipment) chargeable to fire service—		
Source of water supply	$66,482,220	
Distributing system (2,016,927 tons of metal)	127,236,668	
Hydrants (350,152)	29,761,400	
Separate high-pressure fire service	22,191,388	
		[d] 245,671,676
Total cost of fire departments (construction and equipment)		107,063,524
Total cost (construction and equipment) of private fire extinguishers, automatic sprinklers, etc		50,000,000
Total investment in construction and equipment		402,735,200

A study of this table shows that 22 per cent of the total expenditure on behalf of public water supplies is due to additional supplies necessary for protection against fires of such magnitude as may be propagated beyond the building of origin. It will be incidentally noted that there are 2,000,000 tons of metal, having a value in excess of $127,000,000, and the metal in 350,000 hydrants, having a value of nearly $30,000,000, all of which is wasted on account of the need of preparation to fight fires of a kind which, because of the inflammable character of building construction in this country, would develop into conflagrations without adequate water service and fire departments.

---

[a] The amount paid by insurance companies on account of fire loss was $114,164,469, and the amount received by them in premiums was $259,768,831.

[b] $245,671,676, cost of waterworks, chargeable to fire service, capitalized at 4 per cent interest, is equal to an annual charge of $9,826,867.

[c] $107,063,524, cost of fire departments, capitalized at 4 per cent interest, is equal to an annual charge of $4,282,540.

[d] This is 22 per cent of the total cost of water systems, domestic and fire service combined.

The annual cost of maintenance of fire departments in European cities is set forth in the following table, from which it is apparent that the average annual cost in European cities is 20 cents per capita. Compared with this, the average cost in cities in the United States having a corresponding population of 100,000 and over and an aggregate population closely approximating that of these European cities, shows a per capita cost of $1.53, or seven and one-half times the cost of public fire protection over and above that found necessary in Europe.

Annual cost maintenance of fire departments in European cities.

City.	Population.	Fire department maintenance.	Per capita.
Kiel and suburbs	171,000	179,002m. = $42,602	$0.25
Cologne and suburbs	458,037	509,609m. = 121,286	.26
Berlin	1,888,848	2,035,346m. = 484,412	.26
Breslau	422,738	465,571m. = 110,805	.26
London	6,580,616	254,045 £. = 1,238,409	.19
St. Petersburg	1,313,300	578,503 r. = 295,036	.22
Paris	2,714,068	2,925,334 f. = 564,589	.21
Stockholm	311,043	269,164K. = 72,135	.23
Budapest	723,322	281,544K. = 57,123	.08
Milan	491,400	431,253 l. = 83,231	.17
Total	15,074,432	3,069,688	[a] .20
Cities in United States having population of 100,000 and over	16,883,435	25,734,386	1.53

[a] Average.

It is reasonable to assume that at such time as building construction in the United States, through the materials used, building codes adopted, and the enforcement thereof, shall have reached a condition similar to that in Europe our annual costs for this one item alone may be reduced from more than $25,000,000 to $3,000,000, or to less than one-seventh of the present total.

It will be noted that the per capita cost in this country and in Europe which make up these total figures are nearly equally divided between the fire losses and the annual expense of fire protection, and that the ratio of these in the United States and in Europe is nearly the same.

NATIONAL VITALITY, ITS WASTES AND CONSERVATION.

By **Irving Fisher**,
Professor of Political Economy, Yale University.

ACKNOWLEDGMENTS.

The materials upon which this report is principally based were collected during the last ten years. They are far from complete, and I had expected to make use of them at my leisure for a series of special articles, but the opportunity which suddenly presented itself of utilizing them in the construction of this report was one which could not be resisted, despite the fact that the time available was only three months. In the endeavor to make the best use of this time I have been compelled in some cases to rely on secondary sources of information. The number of such cases has been greatly reduced, however, through the kindness of colleagues, friends, and correspondents who were appealed to for suggestions, criticisms, and supplementary material. I am greatly indebted to Prof. Lafayette B. Mendel, of the Sheffield Scientific School of Yale University, for helpful comments and detailed criticism of the whole report, and especially of those parts relative to the physiology of nutrition; to Prof. Yandell Henderson, for many helpful suggestions; to Prof. Henry W. Farnam, for suggestions regarding the topics of industrial conditions; to Prof. M. V. O'Shea, of the University of Wisconsin, for carefully revising the major part of the section on school hygiene; to Dr. Charles Wardell Stiles, Chief of the Division of Zoology, Hygienic Laboratory, United States Public Health and Marine-Hospital Service, for information on the extent and burden of the hook-worm disease; to Surg. Gen. Robert M. O'Reilly, of the United States Army, for statistics of army hygiene; to Dr. Prince A. Morrow, of New York City, and to Prof. C. R. Henderson, of the University of Chicago, for carefully prepared notes in regard to "the social evil."

I am indebted to Dr. Herbert E. Smith, dean of the Yale Medical School, for general criticism; and to his colleagues, Profs. Joseph M. Flint, George Blumer, H. L. Swain, and Oliver T. Osborne, for criticism and aid, both general and special.

Among the many others who have rendered very valuable assistance I would especially mention Dr. J. H. Townsend, secretary Connecticut state board of health; Dr. Cressy L. Wilbur, Chief of Division of Vital Statistics, Bureau of the Census; Col. W. C. Gorgas, chief sanitary officer, Isthmian Canal Commission; Dr. J. N. Hurty, secretary of the state board of health of Indiana; Dr. Charles V. Chapin, city health officer, Providence, R. I.; Dr. George H. Simmons, of Chicago, secretary of the American Medical Association; Dr. J. N. McCormack, lecturer of the American Medical Association; Dr. William J. Mayo, formerly president of the American Medical Association; Dr. Henry P. Walcott, president Massachusetts state

board of health; Prof. F. F. Wesbrook, dean of the Medical School of the University of Minnesota; Dr. Henry B. Baker, ex-secretary Michigan state board of health; Dr. William C. Woodward, health officer of the District of Columbia; Dr. George M. Kober, dean of Georgetown Medical College; Dr. Norman E. Ditman, of Columbia University; Dr. J. H. Kellogg, superintendent of the Battle Creek Sanitarium, and his assistants, Dr. J. T. Case and Dr. W. H. Riley; Dr. Richard C. Newton, of Montclair, N. J.; Dr. Luther H. Gulick, of New York City; Dr. W. G. Anderson, director Yale gymnasium; Dr. Charles H. Castle, of Cincinnati, Ohio; Dr. J. P. C. Foster, of New Haven; Prof. Russell H. Chittenden, director of the Sheffield Scientific School of Yale University; Leo F. Rettger, assistant professor of hygiene, Yale University; Dr. George M. Gould, of Ithaca, N. Y.; Dr. Helen C. Putnam, of Providence, R. I.; F. B. Sanborn, of Cambridge, Mass.; Hiram J. Messenger, actuary of the Travelers Insurance Company, Hartford; Mrs. Ellen H. Richards, of the Massachusetts Institute of Technology; Mrs. Frank P. Kinnicutt, of New York City; and William H. Tolman, of the Museum of Safety and Sanitation, New York City.

To the help received from these persons will be due in large measure whatever of value this report may have. I could not, single-handed, have done justice to even a portion of the subject. Except for a few statistical monographs and papers cited in it, I have contributed little original material. It has been my task to interpret material brought together from many sources. Despite all the aid received, I am aware that the report abounds in sins of omission. Great pains have been taken to avoid those of commission. Doubtful material has been eliminated so far as possible, and where exact figures were unobtainable, every effort has been made to see that the statements made should be cautious and conservative.

For aid in the difficult work of incorporating into the manuscript the numerous suggestions received, I am indebted to Profs. J. Pease Norton, William B. Bailey, Fred R. Fairchild, and Dr. L. W. Zartman, of the economic department of Yale University; and to Dr. M. M. Scarborough, of the Yale Medical School, and Dr. F. B. Standish, of New Haven. For criticisms on the form of presentation, I am indebted to Mr. Edwin Bjorkman, of New York City; to Mr. Michael Williams, of Oak Bluffs, Mass.; and to Mr. Herbert A. Smith, of the U. S. Forest Service.

I wish to thank the Interstate Commerce Commission and Prof. Henry C. Adams, the statistician of the commission, for temporarily detailing Mr. Julius H. Parmelee, a member of the Statistical Division of the Interstate Commerce Commission, to the work of compiling the material gathered from various sources. Mr. Parmelee has brought to his work an unusual equipment. His studies have been not only in statistics, but also in hygiene. Added to his knowledge he has enthusiasm for the subjects covered and a keen appreciation of their importance. The aid which he has rendered has been much more than that of mere calculator and compiler. His ability, thoughtfulness, and self-sacrificing devotion have resulted in painstaking work of a high order, without which the report could not have been written in the allotted time.

IRVING FISHER.

YALE UNIVERSITY, *November, 1908.*

SUGGESTIONS FOR READERS.

In order that this report may be read and used as widely as possible, it has been arranged with reference to five classes of readers:

1. The "Contents by sections," the index, and the page headings will facilitate the use of the report for reference purposes.
2. The "Abstract" is chiefly intended for those who have no time to read more.
3. The "Summary" is a somewhat fuller résumé.
4. The "Summary" is also designed to enable those who so desire to read some parts of the report more fully than others. To this end the "Summary" is arranged to correspond to the main report, chapter by chapter and section by section. The reader who, after reading any particular part of the "Summary," wishes to read the corresponding part of the main report has only to turn to the chapter or section having the same number.
5. Those who read the entire report will probably prefer to read the "Summary" or "Abstract" last.

ABSTRACT.

The problem of conserving natural resources is only one part of the larger problem of conserving national efficiency. The other part relates to the vitality of our population. The two parts are closely interwoven. Protection against mining accidents, forest fires, floods, or pollution of streams prevents not only loss of property, but loss of life. The prevention of disease, on the other hand, increases economic productivity.

So far as we can compare vital and physical assets as measured by earning power, the vital assets are three to five times the physical. The facts show that there is as great room for improvement in our vital resources as in our lands, waters, minerals, and forests. This improvement is possible in respect both to the length of life and to freedom from disease during life.

Contrary to common impression, there is no iron law of mortality. Recent statistics for India show that the average duration of life there is less than twenty-five years. In Sweden it is over fifty years, in Massachusetts forty-five years. The length of life is increasing wherever sanitary science and preventive medicine are applied. In India it is stationary. In Europe it has doubled in three and a half centuries. The rate of increase during the seventeenth and eighteenth centuries was about four years per century, during the first half of the nineteenth century about nine years per century, during the latter half of the nineteenth century about seventeen years per century, and in Germany, where medical and sanitary science has reached the highest development, about twenty-seven years per century. The only comparative statistics available in this country are for Massachusetts, where life is lengthening at the rate of about fourteen years per century, or half the rate in Germany.

There is no need, however, of waiting a century for this increase. It could be obtained within a generation. Three-fourths of tuberculosis, from which 150,000 Americans die annually, could be avoided. Eighteen experts in various diseases, as well as vital statisticians, have contributed data on the ratio of preventability of the ninety different causes of death into which mortality may be classified. From these data it is found that fifteen years at least could be at once added to the average human lifetime by applying the science of preventing disease. More than half of this additional life would come from the prevention of tuberculosis, typhoid, and five other diseases, the prevention of which could be accomplished by purer air, water, and milk. In Lawrence, Mass., after the installation of a pure-water supply, the death rate from typhoid was reduced by 80 per cent. For every death thus saved from typhoid, two or three deaths are saved from other diseases.

Judging from the English statistics of illness, we must conclude that at all times in the United States about 3,000,000 persons are seriously ill, of whom about 500,000 are consumptives. Fully half of this illness is preventable.

If we appraise each life lost at only $1,700 and each year's average earnings for adults at only $700, the economic gain to be obtained from preventing preventable disease, measured in dollars, exceeds one and a half billions. This gain, or the lengthening and strengthening of life which it measures, can be secured through medical investigation and practice, school and factory hygiene, restriction of labor of women and children, the education of the public in both public and private hygiene, and through improving the efficiency of our municipal, state, and national health service. Our National Government has now several bureaus exercising health functions, which only need to be concentrated under one department to become coordinated parts of a greater health service worthy of the nation.

SUMMARY.

SUMMARY OF PART I.—*Length of life versus mortality.*

SUMMARY OF CHAPTER I—THE LENGTH OF LIFE.

SECTION 1. *In different places.*—President Roosevelt has pointed out that the problem of conserving our natural resources is part of another and greater problem—that of national efficiency. This depends not only on physical environment, but on social environment, and most of all on human vitality. Modern hygiene is the reaction against the old fatalistic creed that deaths inevitably occur at a constant rate. The new motto is that of Pasteur: "It is within the power of man to rid himself of every parasitic disease."

It was once believed that human mortality followed an "inexorable law." Facts, however, show that mortality varies in different places and is decreasing as hygiene comes into use. The length of life in Sweden and Denmark is over fifty years; in the United States and England about forty-five; in India less than twenty-five.

SEC. 2. *At different times.*—In Europe, according to one authority, the length of life has increased in three hundred and fifty years from less than twenty to about forty years; in England, in less than half a century, it has increased about five years; in Prussia, in the last quarter of a century, over six years; in America it has also increased, although good life tables are lacking excepting for insurance experience. The tables for Massachusetts for 1893–1897 show an average duration of life in that State of forty-five years, as compared with forty in 1855, and thirty-five, an estimate of 1789, based, however, on doubtful returns.

SUMMARY OF CHAPTER II—THE MORTALITY RATE.

SECTION 1.—*Relation of longevity to mortality.*—As duration of life increases the death rate decreases. A death rate is the ratio of the number of deaths in a year to the population. Under normal conditions where the population is "stationary"—that is, neither increasing nor decreasing nor subject to immigration or emigration—the death rate and the duration of life are "reciprocals." In such a population, if the death rate is 20 per 1,000, the duration of life will be 1,000÷20=50 years.

This relation, however, is disturbed in most countries to-day, and especially in America, by immigration and emigration and by the birth rate being in excess of the death rate. Nevertheless, death rates, if compared under similar conditions, furnish a fairly good index of vitality. They vary in different places and at different times.

SEC. 2. *Mortality in various regions.*—In the registration area of the United States the death rate is 16.5 per 1,000; in France it is 20; in India 42. In different States of the United States it varies from 14 in Michigan to 18 in New York.

SEC. 3. *Urban and rural mortality.*—The death rate is higher in the city than in the country, and the larger the city the higher the death rate. In European countries among the cities with the highest death rate are Dublin (40) and Moscow (37); among the lowest, Frankfort on the Main (16) and The Hague (16).

SEC. 4. *Race and condition.*—The colored death rate greatly exceeds the white. The death rate among the poor exceeds that among the rich, being in Glasgow and Paris over twice as great.

SEC. 5. *Mortality historically.*—Death rates have been decreasing during several centuries. In London, where now the death rate is only 15, it was during the seventeenth and eighteenth centuries 40 to 50, and during 1680 to 1728, a period of pests, it rose as high as 80. Similar reduction has also been experienced in this country. In Habana the death rate after the American occupation fell from over 50 to about 20.

SEC. 6. *Adult and infant mortality.*—The greatest reduction has been effected among children, although the death rate is still undoubtedly high. Statistics show that during the last thirty years the death rate up to 50 years of age has decreased, but that beyond 50 it has remained almost stationary.

SEC. 7. *Particular diseases.*—The mortality from certain special diseases has greatly decreased. The tuberculosis death rate is now in England only one-third of what it was seventy years ago. The death rate from pneumonia now equals that of tuberculosis. Typhoid fever is decreasing. In Munich during 1856 the mortality was 291 per 100,000 of population. The city at that time contained many cesspools. After these were filled up the typhoid rate fell to 10 per 100,000 in 1887, making a reduction of 97 per cent. In Lawrence, Mass., after the public water was filtered in 1893 the typhoid-fever rate fell from 105 to 22. Doctor Kober has shown that death rates from typhoid fever are greatest in cities in which the rivers' waters are polluted, the average for these cities being 62, as compared with 18 for cities using unpolluted water of impounded and conserved streams. Doctor Rosenau concludes that any community having clean water and uninfected milk supply may be free from typhoid.

Smallpox has greatly decreased since vaccination has been employed. In Prussia the death rate per 100,000 from smallpox between 1846 and 1870 was 24. In 1874 vaccination was made compulsory, and the death rate for the years 1875–76 fell to 1.5. Similar figures can be given for other places. The present outcry against vaccination is based on misinformation and on the general reasoning that it is unnatural to introduce a poison into the blood. Statistics show clearly that vaccination decreases smallpox and lengthens life. Even though it were shown that the virus is injurious, it would be the lesser of two evils.

Yellow fever in Philadelphia in 1793 caused the death of one-tenth of the city's population within six and one-half weeks. In 1900 it was found that a species of mosquito transmits this disease. The result of this applied knowledge is that the disease has practically disappeared in America.

SUMMARY OF PART II.—*Breadth of life versus invalidity.*

SUMMARY OF CHAPTER III—PREVALENCE OF SERIOUS ILLNESS.

SECTION 1. *Loss of time.*—Life is shortened by death and narrowed by invalidity. The ideal life, with respect to health, would be free from illness and disability of every kind. To approximate such an ideal is the aim of hygiene. It is usually true that the healthier a life the longer it will last. Humboldt maintained that he had lived four working lives by retaining a working power double the average for double the average number of years. According to Farr, for every death there is an average severe sickness of two years, or for each death per year there are two persons sick throughout the year. This would mean in the United States that, as there are about 1,500,000 annual deaths, there will always be about 3,000,000 persons on the sick list, which is equivalent to about thirteen days per capita.

SEC. 2. *Particular diseases.*—There are constantly ill in the United States of tuberculosis about 500,000 persons, of whom about one-half are totally incapacitated, while the remainder are half incapacitated. The causes of various diseases are closely interwoven. Professor Sedgwick tells us that "Hazen's theorem" shows for every death from typhoid fever avoided by the purification of a polluted water supply two or three deaths are avoided from other causes. Hook-worm disease in the South is a chief cause of incapacitation, especially among the poor whites. For this reason the hook worm has been nicknamed the "germ of laziness." It is believed that a sufferer from hook-worm disease is incapacitated from one-fourth to one-half of the time.

The number of syphilitics in the United States has been estimated at 2,000,000, though from the nature of the case this figure is chiefly conjecture. The social diseases, syphilis and gonorrhea, are responsible for the existence of a large proportion of defectives of various kinds which fill our institutions. Among the troops in the Philippines the venereal morbidity, during the year 1904, was 297 per 1,000, largely exceeding the morbidity from malarial fevers and diarrhea, as 22 out of every 1,000 soldiers were constantly ineffective from venereal disease—four times as many as from any other disease. The statistics outside of army and navy service are impracticable, but there is some reason to believe that they might show an even larger morbidity. The social diseases, which certainly are preventable, are one of the gravest of the menaces to national efficiency.

American railways in 1907-8 killed nearly 11,800 and injured nearly 111,000 persons. The deaths and disablements from accidents in industry, although less carefully recorded, also represent a great and needless impairment of efficiency.

SUMMARY OF CHAPTER IV—PREVALENCE OF MINOR AILMENTS.

SECTION 1. *Importance of minor ailments.*—Minor ailments are far more common than most persons realize. They are chiefly functional disorders, such as of the stomach, heart, nerves, liver, kidney, etc. These deserve more attention than they have hitherto received, because they are the gateway to more serious troubles. For instance, those who neglect colds, or what seem to be colds, will be far more likely to become victims of tuberculosis or pneumonia. No statistics of the prevalence of minor ailments exist. Physicians, whose experience gives them good opportunity to judge, place the time lost annually for each person from minor ailments at three or more days a year.

SEC. 2. *Preventability of minor ailments.*—Practically all minor ailments can be avoided by proper hygiene, public and private. Neurasthenia, so common in America, is one of the most serious and insidious introductions to grave disorders, and is usually due to needless worry or failure to have adequate recreation.

SUMMARY OF CHAPTER V—PREVALENCE OF UNDUE FATIGUE.

SECTION 1. *Strength, endurance, and fatigue.*—Strength is measured by the force a muscle can exert once; endurance by the number of times it can repeat an exertion requiring a specified part of the strength. Fatigue is a chemical effect, due to "fatigue poisons." Far greater differences exist between different persons in respect to endurance than in respect to strength. Some "well" people become tired by a short walk, while others withstand hours of walking, running, or climbing.

SEC. 2. *Alcohol and fatigue.*—The "Committee of Fifty" found that alcohol gives no persistent increase of muscular power. It is well understood by all who control large bodies of men engaged in physical labor that alcohol and effective work are incompatible. Rivers, writing on the influence of alcohol on fatigue, found that when workmen were provided with a moderate amount of wine it resulted in a considerable diminution of their capacity for work.

SEC. 3. *Tobacco and fatigue.*—Athletes recognize that smoking interferes with one's "wind" or "staying power." "Inhaling" tobacco smoke brings carbon-monoxide directly into the blood stream. It is found that smoking increases blood pressure, which fact possibly partly explains the reduction in endurance.

SEC. 4. *Diet and fatigue.*—When excessive amounts of the protein element in food (exemplified in white of egg or the lean part of meat) are taken, they putrefy in the large intestine, producing "auto-intoxication." For this and other reasons, there is a present tendency among physiologists to advise a reduction in the use of such foods from the amounts customary in many countries, and especially in the United States. Auto-intoxication induces fatigue. The endurance of those using high protein and of those using low protein shows in general, although with some exceptions, that the former have less endurance than the latter. Whether the latter are vegetarian or not does not seem to matter. Experiments show that thorough mastication leads instinctively to a reduction in protein.

SEC. 5. *Exertion and fatigue.*—Oxygen, whether taken naturally or artificially, increases the capacity for exertion. A judicious amount of exercise is perhaps the chief factor in producing the highest state of muscular efficiency. Physical training, comprising exercise and other hygienic measures, will probably make the capacity to withstand great exertion three or four times that possessed by most persons.

SEC. 6. *The working day.*—The present working day, from a physiological standpoint, is too long, and keeps the majority of men and women in a continual state of overfatigue. It starts a vicious circle, leading to the craving of means for deadening fatigue, thus inducing drunkenness and other excesses. Experiments in reducing the working day show a great improvement in the physical efficiency of laborers, and in many cases results in even increasing their output sufficiently to compensate the employer for the shorter day. Several examples of such a result exist, but the real justification for a shorter work day is found in the interest of the race, not the employer. One company, which keeps its factory going night and day, found, on changing from two shifts of twelve hours each to three shifts of eight hours each, that the efficiency of the men gradually increased, and the days lost per man by illness fell from seven and one-half to five and one-half per year. Public safety requires, in order to avoid railway collisions and other accidents, the prevention of long hours, lack of sleep, and undue fatigue in workmen.

SEC. 7. *The importance of preventing undue fatigue.*—The economic waste from undue fatigue is probably much greater than the waste from serious illness. This is because the number of fatigued persons is great enough to more than outweigh the fact that the incapacitation from fatigue is relatively small. Moreover, the relatively slight impairment of efficiency due to overfatigue leads to greater impairment from serious illness. A typical succession of events is, first, fatigue, then "colds," then tuberculosis, then death. The prevention of undue fatigue means the arrest at the start of this accelerating chain of calamities.

SUMMARY OF PART III.—*Methods of conserving life.*

SUMMARY OF CHAPTER VI—CONSERVATION THROUGH HEREDITY.

SECTION 1. *Heredity and environment.*—A wise and farsighted economy will lead the nation to conserve its vital resources by every possible method. These resources depend on two primary conditions, heredity and hygiene, or conditions preceding birth and conditions during life. In other words, vitality is partly inherited and partly acquired. A sound physical and mental inheritance is a greater asset than the inheritance of extraneous advantages like wealth. Even in the Old World a degenerate nobility in the end receives less respect than a virile middle class. The effort to improve vitality reaches its highest point in a nation when its health ideals affect marriage.

SEC. 2. *Eugenics.*—Galton, Pearson, and others are attempting to found the new science of "eugenics," by which is not meant any scheme of general governmental interference with marriage, but the gradual establishment in public opinion of fundamental standards. Just as to-day the marriage of brother and sister is unthinkable, Galton suggests that the time may come when marriage which obviously promotes degeneration will be equally tabooed. The result would be, not to make marriage more artificial, but less. Health, beauty, and vitality are much more natural objects of youthful admiration than titles or wealth, which now exercise, for the most part, a baneful influence on marriage. To lessen the esteem for those false attractions and increase that for natural attractions will tend not only to increase the number of healthy marriages, but to give greater importance to natural and normal love. The effect will be felt both in bringing about a larger proportion of marriages among the healthy and a smaller proportion among the unhealthy. It will also lead to a partial segregation by which the healthy will to a large extent marry among themselves, and thus leave the unhealthy either unmarried or compelled to make alliances in their own class. The result will be, in the struggle for race supremacy, that the healthy, thus separated off from the relatively unfit, will have a distinct advantage both in the number of offspring and in their vitality.

SEC. 3. *Eugenics and law.*—The only government influences which have been seriously suggested by eugenists are two: First, the offering of prizes or bounties to couples who conform to certain standards, in the same way as the French Government has encouraged the increase of its population by offering inducements to couples of the poorer class who raise seven or more children; second, to prevent marriage alliances among criminals, paupers, and the feebleminded. Some laws on these subjects already exist in Connecticut, Michigan, and especially Indiana, where there is a prohibition of marriage of all persons suffering from transmissible diseases. It is also now provided in Indiana that confirmed criminals, imbeciles, and rapists, when it is deemed advisable by experts, shall be unsexed. What such laws might accomplish may be judged from the history of two criminal families, the "Jukes" and the "Tribe of Ishmael." Out of 1,200 descendants from the founder of the "Jukes" through seventy-five years, 310 were professional paupers, who spent in all two thousand three hundred years in poorhouses, 50 were prostitutes, 7 murderers, 60 habitual thieves, and 130 common criminals. The loss of potential usefulness, cost of prosecutions, expense of maintenance of jails, etc., Dugdale estimated to be $1,300,000 in seventy-five years, or over $1,000 for each member of the family. All these unfortunate results could have been avoided had the original criminals in this family been sterilized under a law like that of Indiana.

We have the more agreeable record of excellent human qualities inherited through successive generations in the Darwin, Hohenzollern, and other families.

SUMMARY OF CHAPTER VII—CONSERVATION THROUGH PUBLIC HYGIENE.

SECTION 1. *Municipal hygiene.*—The benefits of improved heredity can be enjoyed only by future generations. But we of the present day may conserve our vital resources through hygiene, practiced in one or all of three ways—public, semipublic, and personal hygiene. The first refers to governmental regulation of health, the second to the professional or institutional care of health, and the third to the private life of the individual and the family. Every city now has its health board, yet few citizens realize that the protection rendered by these boards is more important than the protection by the police or fire departments. Much as is done by these boards, there is enormous room for improvement, both in making regulations and in enforcing them by the aid of a more enlightened public opinion. The abatements of the nuisance and menace from spitting and from vitiation by smoke are cases in point. Pure air is one of the primary necessaries of life, but only a small fraction of our countrymen actually enjoy this boon. To this end proper drainage and garbage removal and clean streets are needed. The transmission of disease by insects, flies, and vermin needs to be checked. A constant cause of mortality, among infants especially, is an impure milk supply. The same danger exists in other dairy products, cream, butter, cheese, and ice cream. In Washington, owing apparently to the enactment of a law in 1895 regulating the sale of milk, the death rate from diarrhea and inflammation of the bowels among children under 2 years of age was reduced from 160 or 170 to 135, then 109, 104, and in 1906 to 97. Similar reports come from many other cities in this country and abroad.

SEC. 2. *State hygiene.*—The regulation of the labor of women and children is usually a state matter. It has been suggested by Doctor Stiles that every woman should be allowed once a month to leave a factory without being asked questions or losing wages. The employment of mothers before and after childbirth should be prohibited, as it is now in a number of European countries. This single reform would help greatly to conserve the vitality of the next generation. Child labor in the South is in many cases the lesser of two evils, the other being exposure to the hook-worm disease on polluted farms. In these cases, the abolition of child labor should be preceded by the abolition of hook-worm disease. Hours of labor have been steadily decreasing, and should be decreased further. Accidents are unnecessarily frequent on our American railroads, as well as in industrial establishments. Statistics do not exist for the latter. Special trades have special dangers. Among such trades are those using lead and other dangerous poisonous chemicals, as well as the dust-producing trades which tend to pulmonary troubles. The dark room tenements are a common means in our large cities of depleting national vitality.

SEC. 3. *Federal hygiene.*—This includes quarantine, the inspection of immigrants and exclusion of those with infectious diseases, administration of government hospitals, of pure-food laws and meat inspection, and cooperation with state boards of health in fighting yellow fever, bubonic plague, etc. Federal power needs extension, however. Our interstate railroads should be improved in respect to the sanitation of sleeping cars, smoking cars, etc.

The movement to secure a more intelligent national organization of health is now being pushed by the President, President-Elect, and Members of Congress, and has found expression in the recent platforms of both political parties. What is needed is that the Federal Government should make the national capital a model of sanitation, should provide for more investigation in health matters and the dissemination of information on the prevention of tuberculosis, etc., should cooperate further with state and municipal authorities, and should check the pollution of interstate streams and prevent the transmission of disease-bearing meats or other food from one State to another. Lastly, it should secure, through whatever constitutional means exist, some method of collecting statistical information as to our national mortality and morbidity. Our shortcomings in this respect are now a national disgrace. There is no accurate record of births in any part of the United States, and that of deaths includes less than half our population. As a statistician has said of one of the States, "It buries its dead people with no more ceremony than it buries its dead dogs." Obviously, no intelligent control of epidemics and other diseases can be made unless the facts in regard to those diseases are known; in other words, unless there exist mortality and morbidity statistics of real value.

SUMMARY OF CHAPTER VIII—CONSERVATION THROUGH SEMIPUBLIC HYGIENE.

SECTION 1. *Medical research and instruction.*—Semipublic hygiene comprises that relating to institutions and the medical profession. The hygiene of the future must depend more on discoveries in preventive medicine than on any other single factor, and institutions such as the Pasteur Institute, the Rockefeller and the Carnegie institutes, and the research laboratories of the Government and universities offer the most promising means of increasing this most useful and practical of all human knowledge. The knowledge is dispensed through medical schools in the training of physicians. These schools are improving so as to introduce more of hygiene and preventive medicine. We are still far, however, from having facilities for training public health officers, or giving them such a degree as D. P. H. (diploma of public health), as is given in England.

SEC. 2. *The medical profession.*—Antiseptic surgery has in the last century been the greatest triumph of the medical profession, and has given it a greater prestige than ever before. It has greatly reduced the mortality from operations, and is illustrated by the figures in army operations. The mortality of the wounded in the Crimean war among English troops was 15 per cent. The mortality in the Transvaal war, 1900–1901, was less than 6 per cent.

In the practice of medicine, the tendency is progressively to give up the use of violent drugs and to depend more on hygiene. Through the modern fight against tuberculosis, physicians have come to prescribe fresh air in their practice generally. They are now turning in like manner to exploit the resources of diet, exercise, bathing, and mental hygiene.

There is danger that these new fields will be preempted by quacks. Many quacks to-day, far from using patent medicines, oppose the use of any drugs whatever. In order that modern hygiene shall be applied by trained physicians, it is necessary that they provide more facilities in this direction. The leaders of the profession are making every effort to raise all members of their profession to their own high standard. This standard not only aims to prevent malpractice and unethical operations, but to set an example to the people in public service and in personal hygienic living.

SEC. 3. *Institutional hygiene.*—Hospitals have done much to prevent disease by segregating infectious cases. Institutions for the deaf and blind and other defectives have led to a better utilization of their powers. Institutional care of the insane has done much, too, but can do more. Mental hygiene as a whole needs to be more carefully studied and taught in all its relations—heredity, alcohol, syphilis, and environment.

The modern sanitarium has become a useful institution for prevention of serious illness, as distinct from the hospital, of which the function has been to cure. Department stores, hotels, and other commercial institutions are installing ventilating and other hygienic apparatus. The churches are also taking part in the health movement, especially the Emmanuel Church in Boston.

SEC. 4. *School hygiene.*—The hygiene of school children is especially important because of its application to human life in its early stages. There is a world-wide movement, led by Switzerland and some other countries of Europe, to obtain and apply knowledge of how to educate the mind without weakening the body. As it is, school children are especially exposed to contagious diseases, which under present conditions often sweep through a whole school before the local health board even hears of it. Quite as serious, if not more so, is the protecting of school children from imperfect seating, lighting, ventilation, and sanitation.

Backward children, with defects of eye, ear, nose, or throat, are numerous, but experiments have shown that the majority could be improved both in intellect and in morals.

In respect to school hygiene, it is not so much lack of knowledge as lack of application of knowledge which is at fault. In order to find and then correct defects of eyes, ears, teeth, etc., and properly apply our knowledge, medical inspection is necessary. Such inspections as have been made disclose an astonishing amount of ill health, the percentage of morbidity being from 20 to 60 per cent. The committee on physical welfare of school children in New

York found that 66 per cent needed medical or surgical attention or better nourishment; 40 per cent needed dental care; 38 per cent had enlarged glands of the neck; 31 per cent had defective hearing; 18 per cent had enlarged tonsils.

Eye strain is a particular evil of civilization, and makes its first appearance in school when the scholar tries to accommodate the eye to the short range which reading requires, but for which the eye mechanism is not well adapted by nature. The evil effects of eye strain are not confined to that organ, but extend to the whole nervous system, and indirectly to the whole organism. Doctor Gould, who has made a special study of this subject, goes so far as to maintain that "eye strain is the chief source of the functional diseases of our citizens."

At present medical inspection is the exception rather than the rule. Only 70 cities in the United States outside of Massachusetts, and 32 cities and 321 towns in Massachusetts, have systems more or less complete. New York employs 150 physicians, who visit each public school once a day to examine children set aside for that purpose by the teacher. In Providence a fresh-air school for children suffering from tuberculosis has been established. The cost of the school per capita is about 50 per cent more than the ordinary schools, but the results justify the expenditure.

Our scholars are being seriously injured by nervous overstrain. Probably this is not because too much work is being required, but because the performance of this work is not accomplished economically. Some experiments seem to indicate that children could accomplish as much intellectually with far less dissipation of nervous energy if they were in the schoolroom about half of the time now spent there. High pressure and long hours are bad economy in schools as in factories.

Playgrounds conserve child vitality and are far superior to formal gymnastics. They provide physical training which accords with child instincts, and keep the child out of mischief and often out of jail. Here, as elsewhere, the suppression by civilized and urban life of the instinct for play and amusement is responsible for much of what we call "crime" and "depravity." In school children should not only be surrounded by hygienic environment, but should be taught the value of hygiene. The suggestion of an annual "health day" or "health week" may prove a fruitful one for this purpose.

SEC. 5. *Voluntary and business organizations.*—Societies to prevent the spread of tuberculosis, social diseases, insanity, etc., or to advocate labor or health legislation (state and national), are now numerous and active. It is being found that philanthropy and profit are not always antagonistic. Labor organizations are connecting the health movement with the eight-hour movement. Farsighted employers are providing social secretaries to watch over the health, comfort, and happiness of their employees, and are often eager for practical suggestions in these matters.

Corporations that have installed apparatus for ventilation and sanitation, even sometimes for the benefit of their machinery rather than their employees, have in known instances gotten back the cost in lessened illness and greater efficiency of work.

An interesting experiment near Paris was that of a mill employing 44 men and 75 women and children. Largely through the services, instruction, and suggestions of a medical officer there was not a single death in three years.

The temperance reform has to-day a powerful impulse in the demands by employers for more efficient labor and by the public for greater safety in travel. Locomotive engineers, conductors, and ship captains who drink can not get employment.

Life-insurance companies may possibly in the future realize their opportunity to make financial gains by participation in the health movement.

Finally, one of the greatest potential agencies for bringing about health reform is the public press. It is already interested and active in the movement, although the good it does is often undone by inserting quack advertising. This not only does direct harm, but often ties the hands of the editor, preventing him from expressing any disapproval of nostrums, however injurious or immoral.

SUMMARY OF CHAPTER IX—CONSERVATION THROUGH PERSONAL HYGIENE.

SECTION 1. *Its importance.*—Personal hygiene is not only of direct importance to the individual, but furnishes the public opinion from which, and from which alone, sound public and semipublic hygiene can spring. Public hygiene will be ineffective unless supported by personal hygiene. The milk and water supply of a city may be ideal as supplied at a dwelling, but may be carelessly contaminated there. Observation shows that many of the world's most vital men and women have practiced hygiene and often thereby turned weak constitutions into strong ones. Cornaro, the Venetian nobleman, about to die at 37, adopted the "temperate life," taking especial care not to overeat. He lived to be nearly, or quite, 100.

SEC. 2. *Branches of personal hygiene.*—Personal hygiene comprises hygiene of environment (air, soil, dwellings, clothing), hygiene of nutrition, and hygiene of activity. The ideal conditions of health require purity in air, purity and proper use of food, and a proper balance between mental and physical activity, rest, and sleep. The present world-wide interest in personal hygiene and physical education is not due to any startling discoveries, but to the rediscovery of the importance of truths long insisted upon by the medical profession.

SEC. 3. *The hygiene of environment.*—The prime factor in environment is the atmosphere. Originally man was doubtless an outdoor animal. Civilization has brought him an indoor environment, and with it tuberculosis. Experiments in hospitals have shown that the agitation of the air by dry sweeping greatly increases bacteria. Air in a confined room may be contaminated by chemicals contained in wall paper, plaster, or mortar. The one place in which the individual has most control over his air supply is the bedroom. The fashion now of sleeping with wide-open windows, or even out-of-doors, is certain to improve American vitality. The windows of living and work rooms also may be open even in winter if a window board is used to deflect the air upward and prevent a cold stratum forming on the floor. The outdoor life or the abundant use of fresh air is an almost certain preventive of colds. This fact was commented upon by Franklin over a century ago, and has been rediscovered many times since, especially in the experience of army troops. The evils of bad air are not confined to its chemical content. A room is sometimes "close" simply because it is hot or overmoist or devoid of any air current.

The effect of air on the skin and of radiation of heat from the body is important. Consequently, a proper use of air involves a proper use of clothing, which needs to be both porous and light.

Closely connected with air hygiene is the hygiene of light. "Where sun and air enter seldom the physician enters often." The lighting of dwellings and schoolrooms is especially important with reference to the eyes. This is true also of even the color and texture of the printed page we read. Probably one-fourth of all educated people in America suffer from disturbances due more or less to eye strain and its numerous indirect effects.

SEC. 4. *The hygiene of nutrition.*—The scientific study of diet has only just begun, and few authoritative results can yet be stated. That diet has a distinct relation to endurance has been rendered probable by many investigations, which seem to show in particular that avoidance of overeating, and especially of excess in protein, and thorough mastication are wholesome rules. In the choice of foods the individual must be given a wide latitude. His own instinct, restored and educated by avoiding food-bolting which blunts it, will probably be a truer guide than the wisest of physiologists. Diseased foods, such as oysters polluted with sewage, may transmit typhoid and other maladies.

SEC. 5. *Drug habits.*—Poisons, whether taken into the body or produced within, are injurious. The commonest form of intoxication is alcoholic. Its evils are becoming more apparent than ever before. As Metchnikoff says, it lowers the resistance of the white corpuscles, which are the natural defenders of the body. It predisposes to tuberculosis and numerous other diseases. The findings of the "Committee of Fifty" for the investigation of the liquor problem are important evidence of the evils of the use of alcohol, and these have not received the attention which they deserve. Absinthe in France is being recognized now as a distinct menace to the nation, and in Germany there is a tendency toward a lessened use of alcohol in all its forms. But the movement against the abuse of alcohol has reached its highest point in America.

The evils of tobacco are less and are less appreciated. Its stunting effects on the growing child are especially harmful.

SEC. 6. *Activity hygiene.*—It is an encouraging sign of the times that baths are coming more into vogue, both through the private bath tub for the wealthy and the public baths for the poor. During the last generation the importance of exercise has come to be acknowledged, due largely to the growth of modern athletics. The athletic ideal of the Greeks was, however, higher than that which now prevails in this country. Overexertion, physical and mental, is one of the chief American faults. The danger signal of fatigue is seldom observed, and the instinct for recreation and amusement is often stifled.

SEC. 7. *Sex hygiene.*—Undue reticence on this subject is responsible for the general ignorance as to the extent to which the abuse of the sex relation is injuring this and every nation, physically, mentally, and morally. Syphilis poisons the blood and affects all parts of the body. It makes the individual a "bad risk" for life insurance companies for several years, and is likely to be transmitted to others through a kiss or through the use of a common towel, while the danger of transmitting from husband to wife, or vice versa, continues for many years. Syphilis is one of the few really hereditary diseases, and the saddest of all facts connected with it is that the guilty parent may escape and the innocent children suffer. Gonorrhœa, while usually cured without apparent impairment of health, destroys fertility, and for years after it has apparently ceased may be rearoused. It is responsible for a large number of the cases of infantile blindness and for a larger percentage of many of the serious troubles of women. The social diseases, while seldom assigned as a cause of death, are known to predispose to other diseases and greatly to shorten life.

SEC. 8. *Personal hygiene in general.*—The cumulative effect of hygiene, or of lack of hygiene, needs emphasis. Breathing, eating, working, and sleeping are matters of daily habit. If they are wrong, the evil, however slight, being repeated every day for many years, produces cumulative effects more subtle, but often more powerful, than the effects of sudden infection or accident.

SUMMARY OF CHAPTER X—ARE HYGIENIC MEASURES EUGENIC?

SECTION 1. *The prolongation of weak lives.*—The question has been raised whether reduction in infant and child mortality will not weaken rather than strengthen the race by interfering with natural selection and favoring the survival of the unfit. It is pointed out that the mortality at later ages of life has not decreased, as has that in the earlier ages. There is probably, however, a sufficient explanation of this in the fact that the improvement in hygienic living has not as yet affected adults as much as children. Parents are quick to apply for the benefit of their children new methods of preventing disease, such as sterilizing milk, but do not take the same precautions for themselves. The hurry and stress of modern life has in fact tended to produce in some respects more unhygienic habits among adults than prevailed under the simpler conditions of a generation ago.

SEC. 2. *Children's diseases impair both fit and unfit.*—It must be borne in mind also that the same children's diseases and other causes which tend to kill the unfit child also tend to injure the proper development of the fit. Consequently a lessening of children's diseases will have the effect of not only prolonging weak lives, but also of prolonging and developing the strong. Statistics, so far as available, appear to show that where infant mortality is the highest, mortality at all ages is high.

SEC. 3. *Fitness is relative to environment.*—What is sometimes called degeneration does not deserve that name. A lessening of physical strength, for instance, can not be called degeneration if conditions under civilization do not require the same physical strength as our barbarian ancestors needed. It is adaptation to existing conditions which measures fitness.

Whatever danger of degeneration there may be from the care of the insane and defective classes can be avoided if the health ideals of the nation are strong and broad enough to meet the situation, for with these high health ideals will come a demand which will prevent the perpetuation of the unfit and through the mere force of public opinion lead in general to healthier marriages.

SUMMARY OF PART IV.—*Results of conserving life.*

SUMMARY OF CHAPTER XI—PROLONGATION OF LIFE.

SECTION 1. *Life is lengthening.*—So far as we can judge from statistics of the average duration of life, it has been on the increase for three hundred and fifty years, and is now increasing more rapidly than ever before. During the seventeenth and eighteenth centuries the increase was at the rate of about four years per century; during the first three-quarters of the nineteenth century the rate was about nine years. At present in Massachusetts life is lengthening at the rate of about fourteen years per century; in Europe about seventeen; and in Prussia, the land of medical discovery and its application, twenty-seven. In India, where medical progress is practically unknown, the life span is short (twenty-five) and remains stationary.

SEC. 2. *Table showing further practicable prolongation.*—It is possible to estimate the effect on the length of life of the partial elimination of various diseases. Using the statistics, experience, and estimate of 18 physicians as to the preventability of each of the list of 90 causes of death, we find that the length of life could easily be increased from forty-five to sixty, an increase of one-third, or fifteen years. This would result in a permanent reduction in death rate of about 25 per cent. The principal reductions would be from infantile diarrhea and enteritis, over 60 per cent of which could be prevented, with the result of an addition to the average length of life of 2.32 years. Bronchopneumonia, also an infant disease, could be prevented to the extent of 50 per cent, whereby life would be lengthened by 0.60 year. Meningitis, which is usually fatal at the age of two, could be prevented by at least 70 per cent, and this prevention would lengthen the average life by 0.60 year. Eighty-five per cent of death by typhoid fever is unnecessary, and if avoided would lengthen life at least 0.65 year. It would be feasible to prevent at least 75 per cent of cases of tuberculosis of the lungs, and thereby to lengthen life by about two years. If the deaths from violence were reduced only 35 per cent, human life would be increased by 0.86 year. The prevention of 45 per cent of cases of pneumonia would lengthen life by 0.94 year. These seven diseases alone could easily be reduced by these amounts so as to lengthen life by eight years. This could be done simply through insistence by the public on pure milk, pure water, pure air, and reasonable protection from accidents.

SEC. 3. *Diagram showing effect of prolongation at different ages.*—If we take the diagram representing the life table of Massachusetts for 1893–1897, we may use it as the basis for constructing an ideal curve to show the effect of prevention if applied according to the ratios of prevention given in the preceding table. The results agree substantially with those found in the table and show that about thirteen or more years could easily be added to the average duration of life. The diagram also shows the extent to which the additional life would fall in different ages. The per cent of life which would fall to the ages between 17½ and 60, taken as the working period, would remain the same, namely, about 55 per cent.

SEC. 4. *Fifteen years a safe minimum estimate of prolongation possible.*—The estimate of fifteen years is a minimum because, first, it takes no account of future medical discoveries, such as a method of curing or preventing cancer and of postponing old age, as would Metchnikoff; second, it takes little account of the cumulative influence of hygiene. The full benefit of hygiene can not be felt until it is practiced throughout life, and not at the approach of specific danger. Most so-called "causes" of death are merely the last straws which break the camel's back. When a pure water supply prevents deaths from typhoid fever, it prevents two or three times as many deaths from other causes. Third, it takes no account of the racial effects of new health ideals leading, in a general way, as they must, to healthier marriages.

SEC. 5. *Need of lengthening human life.*—With increase of knowledge the period of education or preparation for life must constantly increase. This fact creates a need for a longer life, with the later periods of life increased in proportion. The result of such a prolongation will be not the keeping alive of invalids, but the creation of a population containing a large number of vigorous old men. Metchnikoff says, "The old man will no longer be subject to loss of memory or to intellectual weakness; he will be able to apply his great experience to the most complicated and most delicate parts of the social life."

SEC. 6. *The normal lifetime.*—It is usually recognized that human life is abnormally short, but no exact determination has ever been made of what constitutes a normal lifetime. Flourens maintains that a mammal lives five times the length of its growing period, which would mean, since the growing period for man does not cease until about 30, a normal human lifetime of one hundred and fifty years. Another method of estimating normal life is to reckon the length of normal life as the time when old age now sets in, 83 years. But clearly, if Metchnikoff is right in thinking that old age itself is abnormal, the normal lifetime must exceed 83. Many remarkable cases of longevity are on record, but most cases of reputed centenarians are not authenticated. Drakenburg's record was authentic, and he lived to be 146. Mrs. Wood, of

Portland, Oreg., recently died at 120. To what extent these exceptional cases could be made common can not, as yet, be known.

SUMMARY OF CHAPTER XII—THE MONEY VALUE OF INCREASED VITALITY.

SECTION 1. *Money appraisal of preventable wastes.*—Doctor Farr has estimated the net economic value of an English agricultural laborer at various times of life by discounting his chance of future earnings after subtracting the cost of maintenance. On the basis of this table we may construct a rough estimate of the worth of an average American life at various ages, assuming that only three-fourths of those of working age are actually earners of money or housekeepers. It gradually rises from a value of $90 in the first year to $4,200 at the age of 30, and then declines until it becomes negative for the higher ages. This estimate assumes $700 per year as the average earnings in middle life. This is largely conjecture, but is regarded as a very safe estimate. Applying this table to the existing population at various ages in the United States, we find that the average value of a person now living in the United States is $2,900, and the average value of the lives now sacrificed by preventable deaths is $1,700. The latter is smaller than the former because the age of the dying is greater than the age of the living. Applying the $2,900 to the population of eighty-five and a half millions, we find that our population may be valued as assets at more than $250,000,000,000; and since the number of preventable deaths is estimated at 630,000, the annual waste from preventable deaths is 630,000 times $1,700, or about $1,000,000,000. This represents the annual preventable loss of potential earnings.

We saw in Chapter III that there are always 3,000,000 persons in the United States on the sick list, of whom about 1,000,000 are in the working period of life and about three-quarters are actually workers and must lose at least $700, which makes the aggregate loss from illness more than $500,000,000. Adding to this another $500,000,000 as the expense of medicines, medical attendance, special foods, etc., we find the total cost of illness to be about $1,000,000,000 per year, of which it is assumed that at least one-half is preventable. Adding the preventable loss from death, $1,000,000,000, to the preventable loss from illness, $500,000,000, we find one and a half billions as the very lowest at which we can estimate the preventable loss from disease and death in this country. The true figures from the statistics available may well amount to several times this figure, but when statistics are based partially on conjecture, they need to be stated with special caution.

SEC. 2. *The cost of conservation.*—In Huddersfield the annual deaths of infants for ten years had been 310. By systematic education of mothers, the number in 1907 was reduced to 212. The cost of saving these 98 lives was about $2,000, or about $20 each. Gen. Leonard Wood declared that the discovery of the means of preventing yellow fever saves annually more lives than were lost in the Cuban war. The hook-worm disease in the South impairs the earning power of its workmen by 25 or 50 per cent. To restore this earning power costs, by curing this disease, on an average, less than $1 for each case. These and other examples show that the return on investments in health are often several thousand per cent per annum. Probably no such unexploited opportunity for rich returns exists in any other field of investment. An actuary suggests that if insurance companies should combine to contribute $200,000 a year for the purpose of improving the public health, the cost would be one-eighth of 1 per cent of the premiums, and it would be reasonable to expect a decrease in death claims of much more than 1 per cent. Even this 1 per cent would make a profit of more than seven times the expense.

SUMMARY OF CHAPTER XIII—THE GENERAL VALUE OF INCREASED VITALITY.

SECTION 1.—*Disease, poverty, and crime.*—Money estimates of waste of life are necessarily imperfect and sometimes misleading. The real wastes can only be expressed in terms of human misery. Poverty and disease are twin evils and each plays into the hands of the other. From each springs vice and crime. Again, whatever diminishes poverty tends to improve health, and vice versa.

SEC. 2. *Conservation of natural resources.*—The conservation of our natural resources—land, raw materials, forests, and water—will provide the food, clothing, shelter, and other means of maintaining healthy life, while the conservation of health likewise tends in many ways to conserve and increase wealth. The more vigorous and long-lived the race, the better utilization it will make of its natural resources. This will be true for two reasons in particular: First, the greater inventiveness or resourcefulness of vigorous minds in vigorous bodies. Civilization consists chiefly in invention and the most progressive nations are those whose rate of invention is most rapid. Second, the greater foresight and solicitude for the future. As it is usually the normal healthy man who provides life insurance for his family, so it will be the normal healthy nation whch will take due care of its resources for the benefit of generations yet unborn.

SUMMARY OF CHAPTER XIV—THINGS WHICH NEED TO BE DONE.

SECTION 1. *Enumeration of principal measures.*—Federal, state, and municipal boards of health should be better appreciated and supported. Their powers of investigation, administration, and disseminating information should be enlarged. School hygiene should be practiced, and personal hygiene more emphasized. The multiplication of degenerates should be made impossible.

INTRODUCTION.

At the conclusion of his White House address on the "Conservation of Natural Resources," President Roosevelt said:

> Finally, let us remember that the conservation of our natural resources, though the gravest problem of to-day, is yet but part of another and greater problem to which this nation is not yet awake, but to which it will awake in time, and with which it must hereafter grapple if it is to live—the problem of national efficiency.

The conditions on which national efficiency depend may be classified under three heads: Those relating to physical environment, those relating to social environment, and those relating to human nature. Under the first head comes the problem of the conservation of land, forests, minerals, and water. The second comprises social questions, whether political, economic, or religious. The third covers the study of the characteristics of man himself—physical, mental, and moral.

This report falls under the third head, concerning as it does vitality, the measure of life itself, and the basis of all human qualities. The object is to review briefly the condition of American vitality, contrasted with the vitality of other nations; to show the extent to which it may be increased; and to point out the value of such an increase in years of life, enjoyment of life, and economic earnings.

The world is gradually awakening to the fact of its own improvability. Political economy is no longer the "dismal science," teaching that starvation wages are inevitable from the Malthusian growth of population, but is now seriously and hopefully grappling with the problem of abolition of poverty. In like manner hygiene, the youngest of the biological studies, has repudiated the outworn doctrine that mortality is fatality, and must exact a regular and inevitable sacrifice at its present rate year after year. Instead of this fatalistic creed we now have the assurance of Pasteur that "It is within the power of man to rid himself of every parasitic disease," as well as the optimistic writings of Metchnikoff and others.

Many evidences of a world-wide awakening to the importance of improving human vitality can be given. Among them are the recent English parliamentary report of the interdepartmental committee on physical degeneration (prompted by the fact that the English army recruits were decreasing in stature); in America, the many societies and congresses to prevent and control tuberculosis, insanity, alcoholism, social diseases and vice, and infant mortality; the growth of preventive sanatoria, dispensaries, and similar institutions; the establishment of numerous journals of preventive medicine, both technical and popular; the increased attention to the subject of health in the public press; the spread of athletics and the physical training movement; the growth of the custom among city people to organize country clubs, and the increasing popularity of golf and similar recreations; the constant agitation and legislation in reference to child labor, slaughterhouses, impure foods, milk supply, and water contamination; the increased vigilance of health boards; the growth of sick-benefit associations and insurance among working men; the efforts toward improving the sanitary surroundings and hours of labor of workmen, and especially of women and children, and, finally, the movement to secure a national organization of health at Washington.

A number of universities are supporting special investigations in physiology, hygiene, and preventive medicine. Some schools also have placed the allied subjects of domestic science and dietetics on their curricula, while physical education is receiving constantly increasing attention. Within a generation every important college, school, and branch of the Young Men's Christian Association has come to have a gymnasium and classes in gymnastics. Research institutions are being established, such as the Rockefeller Institute for Medical Research, the fund established by Mrs. Sage to study diseases of old age, and the Memorial Institute for Infectious Diseases. The home-economics movement is rapidly growing and seems destined to improve greatly the management of American homes.

The practice of medicine, which for ages has been known as the "healing art," is undergoing a gradual but radical revolution. The change is based on the conviction that an ounce of prevention is worth a pound of cure. As teachers and writers on hygiene, as trainers for athletes, as advisers for the welfare departments of large industrial plants, and in many other directions, physicians are finding fields for practicing preventive medicine. There is a still higher stage of medical science than that of fighting or preventing disease in the individual—the stage which has been called "biological engineering," i. e., the study of the conditions under which the individual may reach his highest efficiency. In the development of this science physicians are turning from private practice to public service and are acting as health officers in federal, state, and city governments, as heads of sanatoria and as medical inspectors of schools, factories, mines, and shops. Even the family physician is in some cases being asked by his patients to keep them well instead of curing them after they have fallen sick.

Finally, we have also the suggestion by Sir Francis Galton of the new science of eugenics, which seeks to study the hereditary conditions of human vitality. He has established a research fellowship on the subject at the University of London. Already Karl Pearson and others have made valuable contributions to the study of human degeneration, the effect of tuberculosis on the race, the comparative number of offspring of various classes, and the extent to which mating is "assortative," so that like marries like.

With all these facts in view it requires no great prophetic vision to see that among the rising generation there will be a great movement to conserve human life and health. The power and success of this movement will depend upon the realization of its stupendous importance. A chief object of this report is, in a conservative and cautious manner, to help make this importance clear.

Part I.—THE LENGTH OF LIFE VERSUS MORTALITY.

CHAPTER I.—*The length of life.*

SECTION 1.—*In different places.*

By those who have never considered the problem, death and disease are accepted as a matter of course. In individual cases it is recognized that a death or an illness might have been prevented, but the idea that the death rate could be changed in any appreciable degree, or controlled, is quite foreign to the mind of the average man. Charles Babbage wrote: "There are few things less subject to fluctuaton than the average duration of life of a multitude of individuals."[a]

If this statement were correct, we should find the average duration of life[b] and the death rate substantially the same in different places and at different times. The facts do not conform to this view. Modern life tables show that the average length of life in the leading countries of the world varies remarkably, as the following figures will illustrate.[c]

Modern duration of life.

Country.	Males.	Females.
Sweden, 1891-1900	50.9	53.6
Denmark, 1895-1900	50.2	53.2
France, 1898-1903	45.7	49.1
England and Wales, 1891-1900	44.1	47.7
United States (Massachusetts, 1893-1897)[a]	44.1	46.6
Italy, 1899-1902	42.8	43.1
Prussia, 1891-1900	41.0	44.5
India, 1901[b]	23.0	24.0

[a] Samuel W. Abbott, M. D.: "Vital Statistics of Massachusetts for 1897," Thirtieth Annual Report of the State Board of Health of Massachusetts, 1898.

[b] Statistiques Generale de la France: Statistiques Internationales, etc., 1907, p. 566. See also J. A. Baines, "The Peradventures of an Indian Life Table," Journal Royal Statistical Society, 1908, Vol. LXXI, part 2, p. 310, where the average duration of life for males is given as 23.6.

When we consider that the average duration of life in India is scarcely more than one-half that of France and less than one-half that of Sweden, we must conclude that the length of human life is dependent on definite conditions and can be increased or diminished by a modification of those conditions.

---

[a] Charles Babbage: A Comparative View of the Various Institutions for the Assurance of Lives, p. 15. London, 1826.

[b] By average duration of life or the life span is meant the average length of life among a large number of persons born taken at random. It is not the same as the average age at death in a community during a year, since that community may contain an abnormally large proportion of infants, or of any other "age group."

[c] Some of the figures, especially those for India, rest on imperfect data, but they are believed to be sufficiently accurate for general comparison.

SECTION 2.—*At different times.*

Striking corroboration of this conclusion is found as soon as we compare the average duration of life at different periods of time. The earliest attempt to discover a law of human mortality appears to be that of Ulpian, a Roman pretorian prefect, about 220 A. D. The meaning of his table is somewhat doubtful, but it is assumed to refer to "expectation of life," which for ages up to 20 is given as thirty years.[a]

This estimate is so crude and vague as to be of little value for comparative purposes. Professor Finkelnburg, of Bonn, estimates that—

> The average length of human life in the sixteenth century was only between eighteen and twenty years, and that at the close of the eighteenth century it was a little over thirty years, while to-day it is between thirty-eight and forty years.[b]

In Geneva the records go back over three centuries showing the following life span:[c]

16th century	21.2
17th century	25.7
18th century	33.6
1801-1883	39.7

Here we see an increase in the span of life of 100 per cent in three or four centuries. The last few decades, moreover, tell a striking story of increase. It is one of the boasts of the nineteenth century that the splendid medical and scientific advances of that period have aided in a distinct lengthening of life.

In 1693 the British Government borrowed money by selling annuities, and in 1790, a century later, it did the same thing. While the first venture proved satisfactory, the second caused a great loss to the Government, owing to the improvement in longevity which had taken place, and which was estimated, for the annuitant class, at 20 years.[d]

If we compare Ogle's English life tables for 1871-1881 with those of Farr for 1838-1854, we find an increase in life span of 1.4 years for males and 2.8 for females.[e]

[d] See Dr. Southward Smith, Transactions British Social Science Association, 1857, p. 498, quoted by Dr. Edward Jarvis, ibid.

[e] R. Mayo-Smith; Statistics and Sociology, p. 178. New York (Macmillan), 1895.

A still greater improvement has been effected since Ogle's figures of 1871–1881:

Lifetime in England and Wales:

Males—	
1838–1854	39.9
1891–1900	44.1
Females—	
1838–1854	41.8
1891–1900	47.8

Similar improvements are observable in other countries.

Lifetime in France:

Males—	
1817–1831	38.3
1898–1903	45.7
Females—	
1817–1831	40.8
1898–1903	49.1

Lifetime in Prussia:

Males—	
1867–1877	35.3
1891–1900	41.1
Females—	
1867–1877	37.9
1891–1900	44.6

Lifetime in Denmark:

Males—	
1835–1844	42.6
1895–1900	50.2
Females—	
1835–1844	44.7
1895–1900	53.2

Lifetime in Sweden:

Males—	
1816–1840	39.5
1891–1900	50.9
Females—	
1816–1840	43.5
1891–1900	53.6

It is difficult to obtain American life tables that go far enough back into history to display increases in the life span similar to those just presented; yet comparisons of Abbott's Massachusetts life tables for 1893–1897 with Elliott's Massachusetts tables for 1855 and Wigglesworth's Massachusetts and New Hampshire life tables of a century ago give us a progressive increase from 35 in 1789 [a] to 40 in 1855 [b] and 45 in 1893–1897.[c] Unfortunately no tables exist for the United States as a whole from which similar comparisons might be made. Good and reliable vital statistics are among our most crying needs. Meech's life tables, based on the census figures of 1830, 1840, 1850, and 1860, showed a life span for the whole country of 42.[d]

[c] Abbott, loc. cit.

[d] Levi W. Meech: System and Tables of Life Insurance, ed. of 1886, pp. 255–259. The figures for life span at different periods given in this paragraph have been secured by averaging the figures for males and females.

The census of 1880 gave some 70 sets of life tables for different registration States and cities. The expectation of life for white males was given for Massachusetts as 44, New Jersey 46, District of Columbia 41, and New York City 33, but in constructing the tables "the census was too prodigal as to quantity and somewhat careless as to quality. It is difficult to separate the wheat from the chaff. The table should have been accompanied by a running criticism. The general defect was that no attempt was made to correct the deficiencies in the returns for infants."[a] The census for 1890 gives only a few life tables, and that for 1900 none.

In striking contrast to these recent increases of the life span in progressive countries is the table for backward India, which showed no advance in twenty years.[b]

Lifetime in India:	
Males—	
1881	23.7
1901	23.6

CHAPTER II.—*The mortality rate.*

SECTION 1.—*Relation of longevity and mortality.*

The average duration of life and the death rate[c] are two complementary magnitudes. An increase in the life span means a decrease in the death rate, and vice versa; in fact, in a "stationary" population (a population in which the annual number of deaths equals the annual number of births, and without emigration or immigration), it will be true that the average duration of life and the death rate are mathematically the "reciprocals" of each other.[d] Thus, if the death rate is 20 deaths per annum for each 1,000 of population (i. e., twenty one-thousandths per annum), the average duration of life would be $\frac{1000}{20} = 50$ years.

If this reciprocal relation between duration of life and mortality held true in every population, it would be easy to translate death rates into average duration of life, and conversely; but unfortunately such a simple calculation is impracticable under conditions existing in America, and even in most countries of Europe. With the exception of France, few countries have even approximately an equality between deaths and births and an absence of emigration and immigration. In America, where the deaths are exceeded by the births, and where there is a large immigration of young men and women in the prime of life, the death rate is smaller than it would be if our population were "stationary." The annual death rate in the United

[b] Baines: "The Peradventures of an Indian Life Table," Journal of the Royal Statistical Society, 1908, Vol. LXXI, pt. 2, p. 310.

[c] A death rate is the ratio of the number of deaths during a year to the population, taken at some point in the year, usually the middle.

[d] For a short explanation of this reciprocal relation, which is more fully explained in works on actuarial science, see Fisher: Mortality Statistics of the United States Census, pp. 149–150. It is interesting to see the graphic interpretation of this reciprocal relation by means of the diagram in Chapter XI of this Report.

States is probably about 18 per thousand[a] of population. The reciprocal of this would be 1,000÷18, or 55 years, which is altogether too high an estimate for the average length of life in the United States.

It is possible to "correct" the death rate for "age distribution" so that its reciprocal will be the true average duration of life, but the calculation is a difficult and tedious one. We are forced, therefore, to get along in most cases with the "crude death rate," or the quotient of the number of deaths in a year divided by the population. This figure is much easier to obtain than a corrected death rate or its reciprocal, the average duration of life.

Our data for death rates are far more voluminous than our data for the average duration of life. Although theoretically death rates are not an unerring indication of longevity, they furnish in practice very valuable information. In a general way death rates may be compared with each other, especially in the same community. For instance, a decrease in the death rate in New York City from one year to another is practically a certain indication of improvement in vital conditions.

SECTION 2.—*Mortality in various regions.*

Forty years ago the variations in the death rates of the different sections of Europe were given by Quetelet[b] as follows:

Death rate per 1,000 population.

Northern Europe	24.3
Central Europe	24.5
Southern Europe	29.7

To-day the death rates of various countries compare with each other as in the following table:

Modern death rates per 1,000 of population.[c]

Denmark (1906)	13.5
Sweden (1906)	14.4
England and Wales (1906)	15.4
United States (registration area) (1907)	16.5
Germany (1905)	19.8
France (1906)	19.9
Italy (1906)	20.8
Japan (1905)	21.9
India (males,[d] 1901)	42.3

As we found in the study of duration of life, so we find here wide variations from country to country. Italy presents a death rate larger by nearly one-sixth than that of the United States, while famine-tortured and plague-ridden India's mortality rate is twice that of France and three times the rates of Denmark and of Sweden.

---

[a] W. F. Willcox: "Death Rate of the United States in 1900," publications of the American Statistical Association, Vol. X, p. 155.

[b] Quetelet, Physique Sociale, Vol. I, p. 281. These figures refer to the experience of different periods between 1801 and 1831.

[c] With the exception of the figures for India, this table is taken from figures furnished by the Bureau of the Census.

[d] Baines, loc. cit., p. 310.

Even the fairly homogeneous population of our registration States in America shows variations in death rates.[a]

Death rate per 1,000 population in 1900.

Michigan	13.9
Vermont	17.0
Massachusetts	17.7
New York	17.9

The death rate in Michigan, at the one extreme, is thus but three-fourths that of New York at the other extreme. This difference may probably be accounted for in part by the difference in the age constitution, as the population for Michigan contains a larger proportion of population in young and vigorous life than does New York.

SECTION 3.—*Urban and rural mortality.*

Comparison of urban and rural death rates also gives us variations.[b]

Death rates per 1,000 population in 1900.

Massachusetts:	
Urban	17.9
Rural	17.1
Michigan:	
Urban	15.3
Rural	13.3
New Jersey:	
Urban	18.8
Rural	15.5

Interesting comparisons may be made of the death rates of American cities varying in size and location. The death rate per 1,000 of population in 1906 was given[c] as 14.2 (probably incorrect) in Chicago, in Boston 18.9, in New York 18.6, and in Philadelphia 19.3. Cleveland, Ohio, was credited with a death rate of but 16, while Cincinnati, in the same State, had 20.8. The causes of such differences are not always attributable to variations in size. New Haven, for instance, a larger Connecticut city than either Hartford or New London, had a lower death rate in 1900 by 2.2 and 2.5, respectively, per 1,000 population. The differences are accounted for partly by differences in age constitution, partly—it is unfortunately true—by differences in the accuracy of the collected statistics, partly by differences in size and location, and partly by differences in the vigilance of the public and private health authorities.

European cities show even greater variations in mortality than these just given for the United States.

---

[a] Twelfth Census of the United States, Vol. III, p. LVIII.

[b] United States Census Bulletin, No. 83, 1901.

[c] Seventh Annual Census Report on Mortality Statistics, 1906.

Death rates of European cities per 1,000 population, 1897.[a]

Locality.	High.	Locality.	Low.
Dublin	39.9	Frankfort on the Main	15.6
Moscow	36.9	The Hague	16.2
Belfast	31.3	Berlin	17
St. Petersburg	31	Amsterdam	17.8

[a] One must doubt, however, the accuracy of some of these figures, especially the Russian. The rates in Moscow and St. Petersburg in 1906 are reported as 25.8 and 25.5, respectively, which do not comport with the rates for 1897.

SECTION 4.—*Race and condition.*

The variations in death rates among different races are well known. The black race, for example, always suffers a higher mortality than the white. In Boston during the half century from 1725 to 1774 the death rate per 1,000 is given as ranging from 56 to 87 for the blacks and only from 30 to 41 for the whites. Thus the maximum white death rate was lower than the minimum black death rate.[a]

In 1906 the death rate per 1,000 in all registration cities having not less than 10 per cent colored inhabitants was 17.2 for whites and 28.1 for blacks.

These racial differences may be ascribed in part to different habits and conditions of life, but probably in part also to varying racial susceptibility to disease.

The relation of social status to the rate of mortality has been often discussed and offers a partial explanation of racial or national variation of death rate. That a well-to-do class, properly fed and clothed and with opportunity for leisure, will be less susceptible to disease and death than a poverty-stricken class, ill-fed and overworked, has been repeatedly shown by statistics. Newsholme has stated,[b] for example, that in Glasgow the death rate among tenants of large houses is much lower than among the tenants of smaller dwellings:

	One and two room houses.	Three and four room houses.	Five rooms and over.
Death rate per 1,000 occupants in 1885	27.7	19.5	11.2

In Paris comparison has been made between two quarters known to be rich, on the one hand, and, on the other, a third quarter known to be poor.

Death rate per 1,000 population.[c]

Rich quarters:	
Elysee	13.4
Opera	16.2
Poor quarter:	
Menilmontant	31.3

---

[a] Lemuel Shattuck, "The Vital Statistics of Boston," p. xiii. Reprinted in "Bills of Mortality, 1810–1849," city of Boston, 1893.

[b] Arthur Newsholme, "Vital Statistics," London (Swan Sonnenschein), 1899, p. 163.

[c] E. Levasseur, "La Population Francaise," Paris, 1891, Vol. II, p. 403.

In Russia a similar comparison has been made between peasants who own no land, those who own less than 13½ acres, those who own between 13½ and 40½ acres, and so on up the scale of proprietorship.[a]

Peasant death rate per 1,000, Government of Voronezh, 1889–1891.

Class of household.	Per 1,000.
Having no land	34.7
Having less than 13.5 acres	32.7
Having 13.5 and less than 40.5 acres	30.1
Having 40.5 and less than 67.5 acres	25.4
Having 67.5 and less than 135 acres	23.1
Having more than 135 acres	19.2

Occupational comparisons are often made; and while they must be handled with great care, especially because of differences in age, the following may be said to display roughly the variations in death rate among social classes.

Death rate of males per 1,000, according to occupations, for registration States, 1900.[b]

Mercantile and trading	12.1
Clerical and official	13.5
Professional	15.3
Laboring and servant	20.2

Special industries have high death rates from special diseases. Among dusty trades, for instance, tuberculosis is very common.[c]

Finally, the experience of industrial life-insurance companies, which deal largely with the poorer classes of society, shows a higher death rate than that displayed by the experience tables of other insurance companies.[d]

Insurance mortality per 1,000.

Age	Ordinary insurance, English experience.	Industrial insurance, Metropolitan Life.
20	7.3	10.5
25	7.8	14.1
35	9.3	17.2
55	21.7	35.2
70	64.9	91.0

We find also great variations in death rates dependent on varying climatic or seasonal conditions, on the prevalence or absence of certain pests, on the fluctuating virulence of specific diseases, and on numerous natural differences. Other significant factors in mortality are historical events, such as wars, plagues, and epidemics. Hard times bring increased mortality, whether due to natural or politico-economic causes. There remain to be mentioned also deaths by accident in all its many forms.

[d] Haley Fiske, "Industrial Insurance," The Charities Review, March 1898, p. 33.

SECTION 5—*Mortality historically.*

Not only does the death rate vary greatly from place to place and from one social class to another, but it changes in a most marked fashion from period to period in history. The records of old cities show that a decided decrease in mortality has been steadily going on. In London, for example, the rate per 1,000 has fallen from 50 in 1660-1679 to 15 in 1905, a decrease of 70 per cent. In the plague years, 1593, 1625, 1636, and 1665, the death rates per 1,000 were 240, 310, 130, and 430.[a] The "black death" in 1348-9 probably swept away half of the population in many localities throughout Europe.[b]

Mortality in London.[a]

Year.	Rate per 1,000.
1660-1679	50
1680-1728[b]	80
1729-1780	40
1905	15.1

[a] Kober, *loc. cit.*, p. 25.
[b] These years include the period of pests.

Within a quarter century London has cut her death rate in half, while Vienna, if we may trust the figures, has within a century reduced her rate from 60 per 1,000 of population to 23.[c] Similarly, the mortality rate in Boston has been lowered from an estimated 34 per 1,000[d] in 1700 to 19 to-day.

Mr. John K. Gore, actuary of the Prudential Insurance Company, shows[e] that the average death rates per 1,000 of population among typical American cities was, for the white population, as follows:

Years.	Death rate per 1,000.
1804-1825	24.6
1826-1850	25.7
1851-1863	28.3
1864-1875	25.4
1876-1888	22.9
1889-1901	21.0

The record even of the last thirty years displays a fall in death rates that may inspire us with buoyant hope for the future. The mortality rate per 1,000 has fallen in Berlin from 33 in 1875 to 16 in 1904; in Munich, from 41 in 1871 to 18 in 1906; and in Washington, from 28 in 1875 to 19 in 1907.[f]

Between 1890 and 1906 New York lowered her death rate per 1,000 from 25.4 to 18.6, and Boston from 23.4 to 18.9. The mortality rate in the whole registration area of the United States fell from 19.6 per 1,000 in 1890 to 16.1 in 1906, although the area in the last-named year included a larger proportion of urban population.

[d] Shattuck, *loc. cit.*, pp. xii-xiv.

[e] "On the Improvement in Longevity in the United States during the Nineteenth Century."

[f] Kober, *loc. cit.*, p. 25.

We have also vital records for the city of Habana, running back over a century. These show that while the death rate in 1802 was given as 54.6 per 1,000, rising in cholera years even as high as 103.4 (1833) and in the last year of Weyler's concentration methods as high as 91, the rate during the eight years from 1899–1906 ranged from 20.4 to 33.6.[a]

These records also show the remarkable and sudden fall that may be brought about by a change in the living conditions of a community. During the three "concentration" years of 1896, 1897, and 1898 the mortality rate per 1,000 was 51.7, 78.7, and 91, respectively. In 1899, the first complete year of American occupation, the rate dropped to 33.6, and since then it has ranged between 20.4 and 24.4. There can be no question that the improvement was almost wholly due to the sanitary reforms introduced by Colonel Gorgas, and the other United States Army surgeons under Gen. Leonard Wood.

The record of American Army sanitarians in the Panama Canal Zone shows as striking results as in Cuba. The death rate in Panama during 1887, when the French canal companies held occupation, ran over 100 per 1,000. In 1906 the death rate was 49 per 1,000, while in 1907 it fell to less than 34. Colonel Gorgas attributes the decrease in the general death rate in great part to improved sanitation, though he adds that "increased wages, better food, and better clothing have no doubt played a considerable part in the general improvement of the health."[b]

SECTION 6.—*Adult and infant mortality.*

Mortality varies greatly with age. The improvement in the city death rate of the past half century has been especially marked among the young.

It is true that in countries of the same degree of civilization the infant death rate is remarkably constant,[c] but this is probably accounted for by the similarity in the methods of feeding of infants. Certainly where there is a difference in conditions there will be found a difference in mortality. Thus, the comparison between the mortality of infants fed on cow's milk and those fed on mother's milk shows that the former is five to ten times that of the latter.[d]

Although the infant mortality rate is probably falling,[e] the decrease is not accompanied by a lowering of the mortality of later life. There is an increased mortality beyond the age of 50 years. In Massachusetts the death rates by age changed during thirty years as follows:

---

[b] Letter from Col. W. C. Gorgas, chief sanitary officer, Canal Zone.

[c] See E. B. Phelps, "A Statistical Study of Infant Mortality," quarterly publication of the American Statistical Association, September, 1908. Mr. Phelps shows the utter unreliability of most statistics of infants under 1 year of age, especially in the United States.

[d] See Harald Westergaard, "Mortalität und Morbilität," Jena, 1901, p. 364.

[e] Edward E. Graham, M. D., "Journal of the American Medical Association," September 26, 1908; also "British Medical Journal," February 1, 1908, p. 271.

Death rate in Massachusetts per 1,000 of population in each age period.[a]

Age.	1865.	1895.
5-9	9.6	6.2
10-14	5.1	3.2
15-19	9.6	5.3
20-29	12.6	7.1
30-39	11.7	9.7
40-49	12	13
50-59	17	20
60-69	33	39
70-79	70	82
80 and upward	168	185

[a] "Vital Statistics of Massachusetts," 1856–1895, p. 755.

Here, while the death rate for all age periods under 40 has materially decreased, the later periods of life have suffered progressive increases in mortality rate.[a]

As Frederick L. Hoffman has expressed it:

> There is, of course, no question whatever that the American death rate, using the term in a very comprehensive sense, has substantially declined within the last fifty years, but it is equally evident that this decline has been at the younger ages, and not during the period of life which, economically, is of the greatest value. There is no doubt that the mortality of adult ages is still decidedly excessive.

The same tendency, viewed from the standpoint of the expectation of life,[b] is disclosed in the study of two Massachusetts life tables, compiled nearly a century apart—one, Wigglesworth's life tables for Massachusetts and New Hampshire in 1789, though not very accurate; the other, Abbott's Massachusetts life tables for 1893–1897.

Expectation of life in Massachusetts.

Age.	1789.	1897.	Age.	1789.	1897.
0	35.5	45.4	60	15.4	15.1
10	43.2	50	80	5.9	6.1
20	34.2	42	90	3.7	3.4
40	26	28.2			

These figures indicate that the expectation of life at the earlier ages is much greater than a century ago, but that for the age of 60 and upward it has remained practically stationary.

---

[a] At first sight it would seem that this increased mortality in later ages could be explained away as due to the larger number of persons who are saved from earlier death and tend to produce a higher mortality at the older ages. I speak of this because very intelligent persons have drawn this conclusion. But it is obviously fallacious, since the figures do not indicate the *number* of deaths in different periods, but the death *rates* in different periods of life per 1,000 at each period. There are, to be sure, as a consequence of saving lives in the past, more old men now living than otherwise there would be, and there will be more deaths, but the figures show that these old deaths have increased faster than the number of old men. This fact raises the suspicion, therefore, that the lives which have been saved by the hygiene of a generation ago are weak lives. Whether this is a tenable hypothesis or not will be discussed in Chapter X.

[b] "Expectation of life" at any given age is the mean after-lifetime of persons who reach that age. Thus 100 persons have an expectation of life of 50 at the age of 10, if the total life to be lived by those 100 persons before death is five thousand years.

English life tables[a] for three decades ending 1900 display the same tendency.

English life tables—Expectation of life.

Age.	1871-1880.	1881-1890.	1891-1900.
MALES.			
0	41.4	43.7	44.1
20	39.4	40.3	41
60	13.1	12.9	12.9
80	4.8	4.5	4.6
FEMALES.			
0	44.6	47.2	47.8
20	41.7	42.4	43.4
60	14.2	14.1	14.1
80	5.2	5	5.1

These tables show that there is improvement at the younger ages for the period 1891–1900 over the period 1871–1880. For ages over 60 there has been a retrogression. It is observable, however, that between the periods 1881–1890 and 1891–1900 the figures for 60 years have remained stationary, and for 80 have slightly improved.

In other words, a baby to-day has in prospect a much longer average lifetime than did the baby of two generations ago; but a man or woman 60 years old has in prospect an average after lifetime no greater than formerly.

The proximate cause of this contrast would seem to lie in the fact that the mortality from many of the diseases of later life has been and is on the increase. The death rates from diabetes, heart disease, and Bright's disease have all doubled in thirty years.[b]

Cancer is probably on the increase,[c] and "to-day one in every 21 men who have reached the age of 35 and one in every 12 women who have reached 35 eventually die of that disease."[d]

In addition, there may be mentioned other diseases, arteriosclerosis, nephritis, apoplexy, paresis, disorders of the liver, and all manner of degeneration, all of them maladies of adult life, and all of them apparently tending to increase.

SECTION 7.—*Particular diseases.*

We turn now to the ravages made by particular diseases in the modern world. The death rate in the United States from tuberculosis of all forms equals the combined death rate from smallpox, typhoid fever, diphtheria, cancer, diabetes, appendicitis, and meningitis.

---

[c] Elie Metchnikoff, "The Nature of Man," English translation, New York (Putnam), 1903, pp. 213, 214; see also "United States Census mortality statistics, 1906," p. 29.

[d] Ditman, loc. cit., p. 38.

The death rate from tuberculosis of all kinds in the registration area was 183.6 per 100,000 in 1907.[a] The rate is high among negroes.[b] Large as these figures are, they represent a considerable decrease since 1900.[c] Tubeculosis is a preventable disease.

On a par with tuberculosis in the number of its victims in this country stands pneumonia.

The mortality statistics of the last census show that in the registration area of the United States pneumonia is responsible for 11 per cent of all deaths. Pneumonia is now known to be a communicable disease, the germ of which is very widely distributed; but there is great need for special researches into the modes of spreading this formidable disease. In the meantime the best protection is to "keep in condition." While the germ of pneumonia is the exciting cause of the disease, predisposing causes are acute or chronic alcoholism, exposure to cold, extreme exhaustion, and debility of any kind.

Typhoid fever is in some places yielding to preventive measures in a most striking manner. The fall in the death rate from typhoid in the registration area from 46.3 per 100,000 of population in 1890 to 33.9 in 1900,[d] and to 32.1 in 1906,[e] may be safely ascribed to improvements in the water and milk supplies of our cities. The surprising reduction of the typhoid-fever death rate in individual cities, resulting from definite improvements in the water supply, gives direct confirmation of this statement.

The typhoid mortality in Munich during 1856 was 291 per 100,000 of population. The city at that time contained numerous cesspools, and the water supply was largely obtained from wells and pumps. From 1856 to 1887 there was great activity in the filling up of cesspools, the abandonment of pumps and wells, and the installation of modern sewers. A pure water supply was also secured, the water being brought from a distance. The typhoid-fever death rate fell in 1887 to 10 per 100,000 of population—a reduction of 97 per cent.[f]

In Hamburg the typhoid mortality for 1880–1892 ranged from 24 to 88, averaging 39.7 per 100,000. In May, 1893, a filtration plant was opened, and the rate fell in that same year to 18. For the five years following it averaged only 7.2, showing a reduction of over 80 per cent.[g]

The introduction of a water filter in the town of Lawrence, Mass., in 1893 was followed by a reduction in deaths caused by typhoid from 105 in 1892 to 22 in 1896, one-fifth the previous figure. Filter-ing the city water in several other American cities has shown abrupt declines in the typhoid death rate almost as remarkable.[a]

[a] For a careful statistical study of tuberculosis see "Tuberculosis in the United States," United States Census, issued for the International Congress on Tuberculosis, 1908. See also "Bulstrode's Report in Thirty-fifth Annual Report of (English) Local Government Board, 1905–6," and Arthur Newsholme, M. D., "Prevention of Tuberculosis," 1908.

[b] For the prevalence of tuberculosis in the negro, see F. L. Hoffman's valuable monograph, "The American Negro," publications of the American Economic Association, August, 1896.

[c] This decrease is shown by the exact figures (not estimated) in the registration area.

[d] Twelfth Census of the United States, Vol. III, p. cxliv.

[e] Mortality Statistics, U. S. Census Office, 1906, p. 30.

[f] Ditman, loc. cit., p. 17.

[g] A. C. Abbott, M. D., "The Hygiene of Transmissible Diseases," Philadelphia, Saunders, 1899, pp. 88–89.

Another method of pointing out the importance of a pure water supply is to compare the mortality rates from typhoid fever of cities that secure water from various sources of supply, as the following table shows:[b]

Death rate from typhoid fever per 100,000 of population, 1902–1906.

4 cities using ground water from large wells	18.1
18 cities using impounded and conserved rivers or streams	18.5
8 cities using water from small lakes	19.3
7 cities using water from Great Lakes	32.8
5 cities using surface and underground water	45.7
19 cities using polluted river water	61.1

> Thus far our studies indicate that typhoid fever will cease to be a "problem" in any community having clean water and an uninfected milk supply, and in which cases of the disease are treated as dangerous and contagious."[c]

Unfortunately such communities are too rare at present.

Perhaps the most common and neglected source of danger of infection from typhoid is the ordinary house fly or, as Dr. L. O. Howard, chief of U. S. Bureau of Entomology, would have us call it, the "typhoid fly."

Smallpox, another disease that yields readily to preventive measures, has decreased greatly in virulence and mortality since the introduction[a] of vaccination. In Prussia, for example, the death rate from smallpox per 100,000 population was 24.4 in the period from 1846–1870. In 1874 vaccination, which up to that time had been only intermittently utilized, was made compulsory, and the death rate per 100,000 fell at once to 1.5 for the years 1875–1886.[d]

Other European States, however, have been more lax than Germany. In 1886 the death rate from smallpox in Switzerland was fifty-fourfold that of Germany; in Belgium, forty-eightfold; in Austria, eighty-onefold, and in Hungary, six hundred and sevenfold.[e]

Babbage[f] states that "it has been shown by M. Duvillard that the introduction of vaccination has increased the mean duration of human life about three years and a half." Before Jenner's utilization of vaccination to guard against smallpox that disease was causing one-tenth[g] of all deaths of the human race, just as does tuberculosis to-day, while "nearly twice as many were permanently disfigured by its ravages. In England 300 per 100,000 population died annually from it. It is computed that during the eighteenth century 50,000,000 people died of smallpox in Europe."[h]

[h] Ditman, loc. cit., pp. 6, 52–3.

Boston was visited twelve times by smallpox epidemics in the century and a half ending 1800.[a]

Yet where vaccination has been made compulsory, or where it is generally resorted to, smallpox has virtually disappeared. The last census reported but 3,500 deaths from smallpox in the United States in 1900. Even as long ago as 1826 Denmark was enforcing the practice of vaccination so vigorously that not a single case had appeared for eleven years.[b] Habana, during the eight years prior to the American intervention, reported 3,132 deaths from smallpox. In 1899, the year following the American entry, there were four deaths, and three more during the next seven years—a virtual uprooting of the disease.[c]

The present outcry against vaccination is based on a misunderstanding, and is one of many evidences of the imperative necessity of the diffusion of correct knowledge among the people on matters of hygiene and preventive medicine. Whether vaccination should be made compulsory is a fair question, but that it is efficacious is not open to question. The argument that because some unvaccinated persons escape during an epidemic all would escape is too absurd to deserve serious consideration.[d]

Yellow fever first appeared in serious form at Philadelphia in 1793, when one-tenth of that city's population died of it in the space of six and a half weeks. Since 1793 the United States has had 500,000 cases, resulting, it is estimated, in about 100,000 deaths. In 1900 it was discovered that a species of mosquito is responsible for the transmission of this fever, and in consequence of this knowledge and its application the disease is now practically banished from this country.[e]

The marked decrease in the death rate from yellow fever in Habana since the American intervention in 1898 is shown in the following table. The deaths from yellow fever numbered 4,420 in the eight years from 1891 to 1898, while in the eight years from 1899 to 1906 they numbered but 465.

		1905	8.0
		1906	4.3

[a] Report of the National Sanitary Department of the Republic of Cuba, 1906, p. 79.

These results have been due partly to the elimination of the contagion-carrying mosquito and partly to the general improvement of the city's sanitary appointments.

A similar contrast might be drawn between the death rates from yellow fever at Panama during the efforts of the French to dig the canal and during the American work under the sanitary regulations of Colonel Gorgas. If the same thoroughgoing measures used in Habana and at Panama were employed among our own people, the resultant blessings would be almost equally striking.

The impressive figures just presented, showing the fall in mortality from so many of the most dangerous diseases, point clearly to the value of preventive measures in the conflict with disease. The fall in tuberculosis mortality is directly due to the growing use of hospitals, which have tended to isolate[a] consumptives, and to a use of our recently acquired knowledge of the efficacy of fresh air and the outdoor life; typhoid fever has virtually disappeared when water and milk supplies have been made pure, the open privy abolished, and flies and other carriers of the specific cause of the disease have been provided against; smallpox has given way before vaccination; yellow fever is fast disappearing now that the agent of transmission is known; while many of the less serious diseases are losing their power, purely owing to preventive methods.

Some diseases, once the scourges of humanity, have practically disappeared from the civilized world.

Scurvy up to the latter half of the eighteenth century decimated the armies and fleets of Europe and afterwards proved a menace to the civilized population. During Anson's famous expedition about the year 1750, 600 out of 900 died, chiefly from scurvy. The use of lime juice and fresh vegetables has practically eradicated the disease.[b]

"Cholera was wont to visit the cities of the Atlantic coast in the past about every ten years, and it was a standing menace to the world every summer. It was not uncommon for the disease to decimate whole towns and cities. Since the discovery of its cause, however, it has been robbed of its terrors, and the children of to-day will probably never know of it except by name."

Malaria has been on the decrease ever since the discovery that the malarial organism is transported by a species of mosquito. Even the five years ending 1906 show a progressive decline in the death rate from malarial fever in the registration area. The figures are 5.4, 4.3, 4.2, 3.9, and 3.5 deaths per 100,000 of population, for the five years in question. In themselves, the figures are so small as to show the virtual disappearance of the disease, at least from the Northern States. It is still very common in the Southern States. Its evil is by no means to be measured by the deaths it causes. It produces chronic disability and predisposes to other diseases.[a]

---

[a] See Arthur Newsholme, "The phthisic death rate," Journal of Hygiene, July, 1906.

[b] Ditman, loc. cit., 14–15.

Finally, the furnishing of pure milk to the infant population of the cities is eliminating year by year the infant scourges—diarrheal diseases and related maladies.

There are of course diseases which show no sign as yet of decreasing. The census volume, "Mortality Statistics of 1906" (p. 29) gives only one important disease (diabetes) as actually on the increase within the registration area, but several which are given as having "fluctuating rates," such as cancer, heart disease, and Bright's disease, seem still to have an upward trend.

It is known that malaria is preventable. Why, then, is it not prevented in the South? Probably for two reasons. First, the facts are not generally known, owing to lack of vital statistics in the Southern States. Second, owing largely to this ignorance no adequate effort has yet been made. As an example of what can be done we have the cleaning of Habana by Colonel Gorgas. The following table, supplied by him, shows the deaths from malaria from 1899 to 1907:

Year.	Number of deaths.	Year.	Number of deaths.
1899	909	1904	44
1900	325	1905	32
1901	151	1906	26
1902	77	1907	[a]23
1903	51		

[a] Annual Report of the Sanitary Department for the City of Habana for the year 1907.

"The first year quoted, 1899, the malarial deaths were excessive, owing to the crowding into the city of the 'reconcentrados' and the starvation and misery thereby involved.

The next year, 1900, was about the normal rate. The next year, 1901, begins to show the effect of the antimalarial work done in connection with the yellow-fever work; 1901 was the first year of mosquito work in Habana. The last year, 1907, shows only 23 deaths from malaria. This means practically the extinction of malaria in Habana. The item of 23 deaths in 1907 from malaria would probably be covered by the malarial cases coming in from the rural districts and by mistakes in diagnosis."

The preventability of accidents is beginning to be appreciated. It is now proposed by Mr. W. H. Tolman to establish in New York a museum of safety and sanitation to demonstrate this fact. Mr. Frederick L. Hoffman, statistican of the Prudential Insurance Company, estimates the number of deaths among male workers alone in 1908 as between 30,000 and 35,000.[b]

Part II.—THE BREADTH OF LIFE VERSUS INVALIDITY.

CHAPTER III.—*Prevalence of serious illness.*

SECTION 1—*Loss of time.*

Length of life is but one indication of vitality. Everyone recognizes that the life of a valetudinarian or an invalid, however long, is but a narrow stream. We may therefore conceive, besides the dimension of length, another dimension of life which may be called its "breadth." By the breadth of life we mean its healthiness. Just as length of life is limited by and opposed to mortality or death, so breadth of life is limited by and opposed to invalidity or illness.

An ideally healthy life, free throughout from ailment and disability, is rarely if ever found. But it is the aim of hygiene to approximate such an ideal. Some persons imagine that length of life can be purchased only at the expense of breadth, and counsel the deliberate shortening of one's life for the sake of living it faster. In exceptional cases such a policy may be justified, but the study of longevity reveals the fact that, as a rule, length and breadth of life are not opposed, but that, on the contrary, the one can seldom be increased without an increase of the other. Centenarians are usually persons who have been exceptionally free from illness[a] and who have performed a large amount of work. This work is usually physical labor out of doors, although the few mental workers completing the century have also lived busy lives.

Chevreul, the distinguished French chemist who died twenty years ago at the age of 103, lived a life of great activity and usefulness as laboratory experimenter, as industrial chemist, as university professor, and as a writer and lecturer. It was said of Alexander Von Humboldt, who was 90 at the time of his death, that he had not only lived twice as long as others in years, but that in work accomplished he had lived twice as much per day, thus enjoying four times the average lifetime.

It is shortsighted to spend more vitality each day than we earn. Such a policy must not only prove suicidal sooner or later, but tends to narrow one's life in every way long before the arrival of death. The ordinary individual burns the candle at both ends. The result is an almost universal invalidism in some degree. While statistics are lacking, a wide observation seems to justify the conclusion that it is difficult to find a man or woman over 40 whose health has not become impaired in some manner. Few who have not studied the facts realize how common illness is, although we all know it is sufficiently common to make the question "How are you?" the ordinary form of salutation.

---

[a] Metchnikoff, "The Prolongation of Life," English translation, New York, (Putnam's) 1908, p. 145.

Serious illness is such as totally incapacitates a person from work, whether or not he is confined to his bed. The burden of serious illness is felt in several distinct ways. There is the annual idleness entailed by this illness, the cost of maintaining institutions devoted to the care of the sick, and the cost to the individual of medicines, medical service, and nursing.

The amount of invalidity or illness in a community has been estimated by a number of different investigators, and in a number of different ways. While the results vary somewhat, on the whole they harmonize fairly well.[a]

The most careful consideration of the various illness statistics available was made by Farr. He finds that the rate of invalidity increases with age, and at the later ages increases with great rapidity. The material he has used has come chiefly from various friendly societies in Great Britain and Scotland, and especially from the East India Company. His final conclusion is probably nearly as valid to-day as then. It is that corresponding to each death in a community, there are a little more than two years of illness.

Another way of expressing the same fact is that for each annual death, there are on the average two persons constantly sick during the year. Applying this estimate to the United States,[b] in which about 1,500,000 persons die per annum, there are probably at all times about 3,000,000 persons seriously ill. This means an average of thirteen days per annum for each inhabitant.[c]

Returns gathered from 79 benefit societies in Scotland, aggregating over 100,000 members, and based on the experience of various periods between 1750 and 1821, showed that the average duration of sickness for each member under seventy years of age was ten days per year, 2 of which were assumed to be "bedfast" days, five as days of walking sickness, and three as days of permanent sickness.[d]

SECTION 2—*Particular diseases.*

It has been estimated that the number of persons in the United States constantly suffering from tuberculosis reaches 500,000. Of this number probably about half are totally incapacitated, while the remainder are able to earn about half of the ordinary wages.[e]

---

(Longmans), London, 1887, Vol. I, p. 57; Mayo-Smith, "Statistics and Sociology," New York, (Macmillan) 1895, p. 158; "Statistische Jahrbuch für das Deutschen Reich, 1908," pp. 304–305.

[b] Judging from the experience of sickness insurance, there is more sickness in the United States than in England. See Dr. Edward Jarvis, "Political Economy of Health," Fifth Report of Mass. Board of Health, 1874. Dr. Jarvis also points out that estimates of illness are based on experience of provident persons among whom illness is a minimum, and that the estimates of illness take no account of chronic ailments or "decreptitude."

[c] Farr, Vital Statistics, p. 513.

For every death from typhoid fever, there are about 8 cases of illness, averaging seventy-five days of incapacity. But this is not the only loss. Professor Sedgwick has said, "Hazen's theorem asserts that for every death from typhoid fever avoided by the purification of a polluted public water supply two or three deaths are avoided from other causes. Working under my direction Mr. Scott MacNutt has recently been able to confirm this surprising theorem, and even to establish it as conservative. We have also gone further than Hazen and discovered what the other causes are from which deaths are thus avoided; and, although our results are not yet all published, I may say that conspicuous among these are pneumonia, pulmonary tuberculosis, bronchitis, and infant mortality."[a]

The prevalence of the hook-worm disease in the South has been a matter of investigation for several years by Doctor Stiles[b] of the Public Health and Marine-Hospital Service. The disease is remarkable not so much for its fatality, though that is large, as for the chronic incapacity for work which it produces. For this reason the hook worm has been nicknamed the "germ of laziness." The disease extends over the whole South, and is responsible for a large part both of the sickness (the so-called "laziness") and of the poverty of the "white trash."

There are no satisfactory statistics as to the extent of hook-worm disease; but it has been estimated that the sufferers are incapacitated for labor from one-fourth to one-half of their time. Most striking is the fact that the disease is easily preventable through the introduction of sanitary measures as well as curable by the proper (drug) treatment of the present victims. It has been largely eradicated from Porto Rico.[c] Hook-worm disease weakens when it does not kill and is known to be a precursor of tuberculosis.

Malaria is one of the diseases which are fatal relatively seldom, but which shorten life by predisposing to other causes of death, and narrow life by reducing working efficiency by a large percentage. Doctor Howard states that each year there are probably 3,000,000 cases of malaria in the United States, most of which are in the South. This is practically all preventable.[d]

Dr. Prince A. Morrow says that the number of syphilitics in the United States has been estimated at 2,000,000. This disease is not only in itself a danger, but it also causes a large number of diseases of the circulatory and nervous systems.

Doctor Morrow says that the extermination of social diseases would probably mean the elimination of at least one-half of our institutions for defectives. The loss of citizens to the State from the sterilizing influence of gonorrhea upon the productive energy of the family, and the blighting destructive effect of syphilis upon the offspring are enormous. In the opinion of very competent judges social disease constitutes the most powerful of all factors in the degeneration and depopulation of the world.

[c] "Reports of Commission on the Suppression of Uncinariasis, 1904, 1905, 1906-7, 1907-8, San Juan, P. R." This commission has been succeeded by a bureau, the "Anemia dispensary service."

[d] See L. O. Howard, Report to Conservation Commission, "Economic loss to the people of the United States through insects that carry disease."

Among the troops stationed in the Philippines, the venereal morbidity during the year 1904 was 297 per 1,000, largely exceeding the morbidity from malarial fevers and diarrhea; 22 out of every 1,000 soldiers were constantly ineffective from venereal diseases, four times as many as from any other disease.

The statistics of the Navy Department show during the same year, that venereal disease was chargeable with a percentage of 25.2 of the total number of sick days in the hospital from all causes combined. In four years 949 men were discharged from the navy for disability from venereal disease. The statistics of the English army show that among the troops stationed in India 537 per 1,000 were admitted to the hospital for venereal disease. Of the troops returning home to England after completing their time of service in India, 25 per cent were found to be infected with syphilis.

No statistics exist for venereal disease in civil life. It may be more prevalent than in the army and navy service, since the inhibitory influence of military restraint and discipline do not exist and the opportunities for licentious relations are more abundant.

Neisser, a distinguished German authority, states that "fully 75 per cent of the adult male population contract gonorrhea and 15 per cent have syphilis."

What syphilis and gonorrhea represent in the lowered working efficiency of our population—to say nothing of the still more important subject of increased mortality—is impossible to estimate; but it would be difficult to overemphasize the grave danger to national efficiency from these and the other venereal diseases. And here again the most striking point is that the venereal diseases are preventable.

Alcoholism and drug addiction are maladies of frightful prevalence. They are so familiar as to be taken by many as a matter of course.

Venereal diseases and inebriety, whether alcoholic or drug, frequently lead to insanity. Statistics are not yet able to prove conclusively that insanity is increasing, though this is the opinion of the best judges.[a]

Dr. C. L. Dana, formerly president of the New York Academy of Medicine, believes the increase in insanity to be real as well as apparent. He says: "The annual increment of insane in Massachusetts, according to the Massachusetts board of lunacy, is 400 in about 10,000, or 4 per cent." At this ratio the annual increment for the United States would be approximately 5,600. "We may say that in the last twenty-five years the ratio of insane to sane has shown an apparent gradual increase from 1 to 450 to 1 to 300, and this latter seems to be about the ratio in those communities of North America and Europe in which modern conditions of civilization prevail. This average has varied but little in the last few years; the slight yearly increase probably will not change rapidly and probably not continue, for when the increase in the insane reaches a certain point of excess society will have to take notice of it and correct it."[b] There are no accurate figures of the number of insane. Mr. Sanborn estimates that the number exceeds 250,000 in the United States.

---

[a] For a critical examination of statistical data on insanity, see Humphreys (Noel, A.), "The alleged increase of insanity," Journal of the Royal Statistical Society, June, 1907.

[b] "Psychiatry in its Relation to Other Sciences," section on psychiatry at the International Congress of Arts and Sciences, St. Louis, September, 1904.

Among defective and disabled classes are to be especially mentioned the feeble-minded, paralytic, crippled, blind, and deaf mutes. The aggregate disability of these groups is greater than is commonly recognized. The preventability is still less appreciated.

With reference to the losses each year from industrial accidents:

The statistical report of the Interstate Commerce Commission for the year ending June 30, 1907, shows that during that year 11,800 persons were killed and 111,000 injured on our American railways, these figures including passengers, employees, and all other persons. A large number of the victims were railway employees, for whose safety Congress has passed a number of laws. The total number of cases of industrial accidents can not be estimated, owing to the lack of statistical information; but Census Bulletin 83 gives the number of deaths by accident and violence in 1900 at 57,500.

"Of 29,000,000 workers in the United States over 500,000 are yearly killed or crippled as a direct result of the occupations in which they are engaged—more than were slain and wounded throughout the whole Russo-Japanese war. More than one-half this tremendous sacrifice of life is needless."[a]

Mr. Frederick L. Hoffman estimates[b] that the number of accidents among men employed in the United States in 1906 was 208,000, of which about 5,000 were fatal. These figures are exclusive of mining, railway, and shipping accidents.

John Mitchell[c] estimates that for every 100,000 tons of coal produced in the United States one mine worker is killed and several injured. In 1907 the figures were 2,500 coal miners killed and 6,000 seriously injured.

In Wisconsin from October 1, 1906, to October 1, 1907, the total number of accidents reported which incapacitated the victim by at least two weeks was 13,572. The accidents to employees constituted 53 per cent of this number.[d]

Special trades have special perils for workmen. "Among diseases to which workmen are most often subject are the so-called 'inanition, scrofula, rachitis, pulmonary consumption, dropsy;' also rheumatic troubles, pleurisy, typhoid fever, gangrene, and the various skin diseases. Every epidemic, be it typhoid, smallpox, scarlet fever, dysentery, cholera, etc., draws its greatest army of victims from this class. For every death that occurs among the richer and higher classes there are many in the working class. It is the workman engaged in unhealthy factories first of all who fills the hospitals and their death chambers."[e]

It is the pollution of the air breathed by workmen, whether the pollution come through poisons or through dust, that makes many trades dangerous. Among poisonous trades are the many lead-using industries, foundries, and chemical factories. Investigations of the dust-producing trades have been made, showing the results on the respiratory systems.

[e] C. F. W. Doehring, "Factory Sanitation and Labor Protection," Bulletin Department of Labor No. 44, January, 1903, p. 2.

Hirt's statistics show that men employed in dust-producing occupations suffer much more frequently from pneumonia and consumption than do those not exposed to dust. The relative frequency of these diseases per 100 workmen is as follows:

Cases of consumption and pneumonia per 100 workers in certain occupations.

	Consumption.	Pneumonia.
Workers in metallic dust	28	17.4
Workers in mineral dust	25.2	5.9
Workers in mixed dust	22.6	6.0
Workers in animal dust	20.8	7.7
Workers in vegetable dust	13.3	9.4
Workers in nondusty trades	11.1	[a]4.6

[a] George M. Kober, M. D., "Industrial Hygiene," Bulletin of Bureau of Labor, March, 1908, p. 477.

Mr. Owen R. Lovejoy, secretary of the national child-labor committee, has condensed a table from Indiana reports[a] showing the high injury rate suffered by children in the industries.

Injuries to children in Indiana, 1907.

Proportion of adults injured	5 per 1,000 3 per 1,000
Proportion of children injured	20 per 1,000 10 per 1,000

The injury rate for children is shown to be three to four times as great as for adults.

CHAPTER IV.—*Prevalence of minor ailments.*

SECTION 1.—*Importance of minor ailments.*

The statistics of morbidity which we have given refer to forms which are relatively acute; but there are many milder forms which do not incapacitate the patient from work or compel him to take to his bed. The extent of these milder ills is not generally appreciated. They are often carefully guarded secrets. The individual often knows only his own physical troubles, but is unaware of the fact that almost every person about him has such troubles also. Once you penetrate beneath conventional acquaintance there will almost invariably be found some functional impairment of heart, liver, kidneys or bladder; or dyspepsia, gastritis, jaundice, gallstones, constipation, diarrhea; or insomnia, neurasthenia, nervousness, neuritis, neuralgia, sick headache; or tonsilitis, bronchitis, hay fever, catarrh, grip, colds, sore throat; or rupture, hernia, phlebitis, skin eruption; or rheumatism, lumbago, gout, obesity; or decayed teeth, baldness, deafness, eye ailment, spinal curvature, lameness, broken bones, dislocations, sprains, bruises, cuts, burns, or other "troubles."

---

[a] "Eleventh Annual Report of the Department of Inspection of Indiana, 1907," Exhibit C, pp. 166–198.

These so-called "minor ailments" will undoubtedly in the next few years receive much more attention than now. Until recently the physician has been accustomed to treat only acute diseases, but as preventive medicine gradually replaces curative medicine the physician will be more called upon to treat minor ailments. These are generally the first warnings of more serious troubles. If what seem to be "mere colds" were less commonly neglected, tuberculosis would more often be caught in its incipiency, and pneumonia and diphtheria would often be prevented.

From the "common colds" also tonsillitis and abscess of the ear can and do come, purulent inflammations of the pneumatic and venous cavities of the face and skull, and meningitis and cerebral abscess—all of which destroy many lives annually; or the lives may be saved by a surgical operation after a serious and prolonged illness. Tonsilitis, in turn, in addition to lighting up furious inflammations in its own immediate vicinity, can be held responsible in a certain number of cases for serious diseases at a distance from its own site. These are septic arthritis (inflammation of joints), septic peritonitis, appendicitis, endocarditis (valvular disease of the heart)—severe and frequently fatal diseases. Gastritis or gastroenteritis, sick headache, jaundice, lumbago, are not usually of serious import, but sometimes are the signs that point to an underlying cause (alcoholism, overeating, chronic protein intoxication, worry—business or domestic—sedentary life, etc.) which will lead later to arteriosclerosis, chronic nephritis, toxic amblyopia (optic nerve blindness), cirrhosis of the liver, cerebral hemorrhage or valvular disease of the heart.[a]

If the first twinges of rheumatic pains were heeded, gout and the dreaded arthritis deformans would lose most of their terrors. We could then arrest a great majority of serious affections at the very gateway. It can hardly be doubted that even such diseases as cancer, whose causation is not yet understood, gain a foothold through lowered vital resistance, manifesting itself at the first in minor ailments of some kind.

The American neurasthenia, widespread and subtle, has its grip on thousands of men and women, driving them from home and offices annually to sanitaria or various health resorts, and so breaking down their average vitality as to render them much more liable to serious sickness and death.

This, the most widely prevalent of all nervous disorders in this country, seems to be on the increase. It is very commonly found among persons who take no reasonable recreation—many business men, among others—and the loss of time and incapacitation for work are very great, often weeks and months at a time.

As to the extent to which minor ailments exist, no statistics are available. Doctor Castle, of Cincinnati, estimates, from an experience of many years in the medical supervision of institution employees and general practice, that there is an average of at least three days' time lost annually for each person in the population because of such minor ailments. Similarly, Dr. J. F. Morse, of the Battle Creek Sanitarium, who has had a long experience in dealing with a large number of cases, estimates that the average "well man" loses on an average five days a year from work on account of headaches, toothaches, "colds," and similar minor ailments which do not come under the head of any of the diseases reported.

---

[a] Letter from Dr. Chas. H. Castle.

SECTION 2.—*Preventability of minor ailments.*

That almost all minor ailments can be avoided is scarcely to be doubted. Doctor Gulick is "inclined to believe that something like nine-tenths of all the minor ailments that we have, and which constitute the chief source of decreasing our daily efficiency, could be removed by careful attention." "With the removal of nine-tenths of our disabilities and the conservation and further development of our natural powers," he adds, "the average person can increase his efficiency 100 per cent, that is, he can be twice as effective. This does not refer to doing merely or mainly twice as much work, of course, but by making less mistakes, and by working at a higher degree of speed when he does work. By working under conditions so that the work does not need to be repeated, the whole total will be much greater—I think not too much to say twice as great—as under ordinary conditions."

Minor ailments are preventable by leading a reasonably hygienic life and by revising the modern gospel of "hustle"—which latter usually means crude, imperfect, and slovenly work, whether mental or manual. The prevention of these diseases would "cost" nothing—for it costs nothing to stay well.

If, again, we consider the experience of those who have made a serious attempt to avoid minor ailments, their preventability becomes clear. Personally, I have known of scores of cases in which the tendency to catch cold has been almost completely overcome. In one case a physician, who as a boy had suffered from continual colds and hay fever, succeeded, through the simplification and control of his diet, in attaining almost complete emancipation, which has lasted over forty years. Another physician reports that for ten years, during which time he has taken special means to produce complete evacuation, he has not caught a single cold. A large number of cases observed are of persons, physicians as well as laymen, who have taken the outdoor cure for tuberculosis or nervous prostration. These persons not only succeeded in combating these serious troubles, but in completely freeing themselves from liability to colds. Evidently, if the outdoor life had been adopted simply as a preventive of colds, it would have prevented originally, as it cured subsequently, their more serious disorders.

CHAPTER V.—*Prevalence of undue fatigue.*

SECTION 1.—*Strength, endurance, and fatigue.*

When a person is free from all specific ailments, both serious and minor, he usually calls himself "well." There is, however, a vast difference between such a "well" man and one in ideally robust health. The difference is one of endurance or susceptibility to fatigue. Many "well" men can not run a block for a street car or climb more than one flight of stairs without feeling completely tired out, while another "well" man will run 25 miles or climb the Matterhorn from pure love of sport. The Swiss guides, throughout the summer season day after day, spend their entire time in climbing. A Chinese cooly will run for hours at a stretch. That the world regards such performances as "marvelous feats of endurance" only shows how marvelously out of training the world as a whole really is. In mental work some persons are unable to apply themselves more than an hour at a time, while others, like Humboldt or Mommsen, can work almost continuously through fifteen hours of the day.

As Mosso[a] and others have proved, muscular fatigue is a chemical effect, due to the circulation of "fatigue poisons" in the blood. This has been strikingly shown by experiments by Weishardt and others on dogs; when blood is transfused from an exhausted dog to a "frisky" one, the latter immediately wilts and becomes fatigued like the former, although he has not exerted himself in the least. In order to reduce fatigue, therefore, we should keep down fatigue poisons. It is not unlikely that almost all poisons produce fatigue, whether the poisons come from infections, from drugs, from impure or excessive food, from bad air, or from exertion.

It should be noted that endurance is a quality quite distinct from strength.[b] Strength is measured by the utmost force a muscle can exert once; endurance by the number of times it can repeat an exertion requiring a specified fraction of available strength at the start. Thus, if each one of two men is barely able to lift a dumb-bell weighing 100 pounds, their strengths are equal, but if one of them can raise a dumb-bell weighing 50 pounds 20 times, while the other can raise it 40 times, the latter may be said to have double the endurance of the former. Another mode of expressing the same thought is that endurance is measured by the slowness with which strength decreases through exertion.

SECTION 2.—*Alcohol and fatigue.*

Of all poisons in ordinary use, alcohol and tobacco are the most common. That alcohol increases fatigue is now commonly recognized by athletes. "Alcohol gives no persistent increase of muscular power. It is well understood by all who control large bodies of men engaged in physical labor that alcohol and effective work are incompatible."[c]

One of the most interesting features of the cycling sport, when long tours were the fashion a few years ago, was the fact that the wayside seller of drinks found himself forced to supply chiefly "temperance drinks." The cyclists discovered that they could not make their "century runs" on alcoholic beverages. Two friends report that they stopped for refreshments and drank beer. Resuming their ride they found it hard to propel the machine, and both imagined some obstruction had lodged in the gears. Only after having dismounted and satisfied themselves to the contrary did they come to the conclusion, whether rightly or wrongly, that the resistance was in their own legs and was due to the beer.

Careful experiments with alcohol in relation to fatigue have been reported by Rivers,[d] who shows that alcohol diminishes the capacity for exertion. Experiments carried on by Professor Aschaffenburg with four typesetters, all users of alcohol, showed that on days when Greek wine, containing 18 per cent of alcohol, was given the men there was considerable diminution of the capacity for work. On the alcohol days two of the men did decidedly less work, while the work of the remaining two was marked by great irregularity.

[d] W. H. R. Rivers: "Influence of Alcohol on Fatigue, etc." London (Edward Arnold), 1908, pp. 89–90.

The injury from alcohol is mitigated, but not excluded, through combination with sugar, malt, and other beneficial ingredients, as in beer.

SECTION 3.—*Tobacco and fatigue.*

As to tobacco it is a common observation that smoking interferes with one's "wind" in running. The poisons which probably bring about this result include others than nicotine. Possibly the most important poison is carbon monoxide, which has a great affinity for the iron in the blood.[a] When the smoker "inhales," this poison, probably joined with others, enters directly into the blood stream.

In an experiment carried on by Doctor Lombard, "smoking was found to have a very depressing effect upon the strength of the voluntary muscular contractions. * * * Undoubtedly the effect of tobacco to lessen the voluntary power is due to its influence upon the central nervous system."[b]

It is the testimony of many users of tobacco that the habit of smoking leads to nervousness and disinclination to exertion directly after smoking.

Experimentation has shown that smoking increases blood pressure. The greater resistance to circulation offered by the blood is presumably due to the excitation caused by the introduction into the blood stream of foreign matter from the tobacco. There is reason to believe, though the fact has not been established, that endurance is lessened by high blood pressure.

SECTION 4.—*Diet and fatigue.*

Poisons may also enter the system through food. Many poisons come from diseased, contaminated, or adulterated foods; but they may also be due to excess of food or wrong preparation of foods, and especially to the decomposition of protein (the principal ingredient of white of egg and lean meat) in the colon. The absorption of such poisons causes auto-intoxication.

It has long been known by physiologists that the putrefaction in the intestines is the putrefaction of protein. But only recently have they raised the question whether a reduction of the protein element of food would be feasible and whether the resulting reduction in putrefaction and auto-intoxication might not be advantageous.[c] These questions are still under debate, but the trend of physiological opinion is increasingly in favor of protein reduction. Practically this means a lessening of the consumption of lean meat and eggs.

[c] See C. A. Herter, "Bacterial Infections of the Digestive Tract," New York (Macmillan), 1907.

Evidence has accumulated, though it has not yet been put in proper experimental form for absolute proof, that auto-intoxication is not only an exceedingly common affection, but also the chief cause of undue fatigue. Most persons know the heavy feeling and disinclination to exertion which generally accompany constipation, and, on the other hand, the relief which comes with a complete evacuation.

Leaving auto-intoxication aside, Professor Chittenden is of the opinion that waste products from combustion of protein are probably responsible for fatigue. Whatever the explanation, Professor Chittenden found in his classical experiment[a] with a squad of soldiers, that strength and endurance were increased by a reduction of the protein. Thirteen soldiers were placed for six months on a diet containing a much smaller quantity of protein food than what is prescribed by ordinary dietary standards and containing only one-third of what is demanded by common American usage. Professor Chittenden's results are gaining recognition, but they will need to be further tested before any unanimity of opinion can be reached.

Analysis of the diet of several hundred vegetarians shows that on the whole they are lower in protein than the average American. Comparative experiments on 17 vegetarians and 25 meat eaters in the laboratory of the University of Brussels have shown little differences in strength between the two classes, but a marked superiority of the vegetarians in point of endurance. The average superiority was 53 per cent. The vegetarians recuperated from fatigue more quickly than the meat eaters.[b] To what extent, if at all, the superiority of the vegetarians was due to vegetarianism as such, and to what extent to the fact that they made a more moderate use of protein, can not be exactly determined, although the evidence indicates that the lower protein is the essential factor. The virtues and drawbacks of vegetarianism as such have as yet received almost no scientific study.[c] Professor Chittenden is now engaged in such a study.

In another experiment, comprising 49 subjects and contrasting those on high and low protein diets, it was found that the low protein subjects had greater endurance.[d] For instance, the test of "deep-knee bending" showed that whereas the high-protein subjects could seldom exceed 400 or 500 times, the low-protein men could frequently exceed 1,000, and in one case reached 2,400.

The writer has in his possession several hundred unpublished individual records of men on a low and high protein diet. These, on the whole, seem to show a considerable superiority in endurance among those using the lesser amounts of protein. But while the trend of evidence seems at present to favor a reduction in protein, the question is not yet settled.[e] There exist many conspicuous cases of high protein and great endurance. A striking instance is that of the pedestrian Weston.

[e] See, for example, Prof. F. G. Benedict's paper on "The nutritive requirements of the body," American Journal of Physiology, Vol. XVI, 1906, pp. 409–437.

In an experiment on nine healthy students, the writer found that thorough mastication seemed to cause a gradual decrease in protein. The significance of the experiment lay in the improvement in physical endurance of eight of the men, which increased over 90 per cent in five months. The ninth man—the only one whose protein was not greatly reduced—failed to improve in endurance.[a]

SECTION 5.—*Exertion and fatigue.*

Exertion increases combustion of oxygen, and the capacity for exertion is intimately related to the completeness of this combustion.

Experiments in artificially administering oxygen to athletes have been made in England by Hill, Flack, Pombrey, and others.[b] Following these, a series of experiments in swimming recently took place at Huntington, L. I. The swimmers to whom oxygen had been administered surpassed their nonoxygenized competitors as well as their own previous natural records. Doctor Bising, who carried on the experiment, states that the effects of oxygen inhalation are useful for short efforts only. At most the oxygen exercises its influence for not more than three minutes.

Perhaps the most important of the common influences affecting the capacity to resist fatigue is physical exertion. It is well known that a man "in training" has greater endurance than one who attempts exertion without previous systematic exercise or training. In general, it may be said that a person in the "pink of condition" is fit not only for physical but also for mental exertion. The great majority of adults are far from being "in condition," suffering either from lack of exercise or from too much exercise. The ordinary man errs either in one direction or the other. The brain worker lives too sedentary a life, while the manual worker, through fatigue caused by long hours, is in a continual state of overexertion. Could these conditions be remedied, endurance, as measured by capacity to withstand prolonged strains, might be greatly increased.

Experiments have shown that physical endurance can be doubled by dietetic causes alone, or doubled by exercise alone. By both together it is not unlikely that it could be tripled or quadrupled. But when it is said that the endurance, or capacity for exertion, of the ordinary healthy man could be thus multiplied, it is not meant that the hours of his daily work, or even his daily output of work, could be increased in such a ratio. What it does mean is the removal of the fatigue limit, a freer and more buoyant life, and a visible increase in the quantity and quality of work per hour.

In an ideal life fatigue would seldom be experienced. But in most lives, unfortunately, fatigue is a daily experience. A workman who gives intelligent and systematic care to the body writes that when after a long day's work the factory whistle blows at night he, unlike his fellows, feels as fresh as when he began work in the morning. Workmen can by such self-care mitigate some of the evils of

"the long day." But they are amply justified, both in the interest of their own and of national efficiency, in continuing their efforts toward a shortening of the work day.

SECTION 6.—*The working day.*

The present working day is a striking example of the failure to conserve national vitality. In order to keep labor power unimpaired, the working day should be physiological—i. e., it should be such as would enable the average individual to completely recuperate over night. Otherwise, instead of a simple daily cycle, there is a progressive deterioration. A reduction in the length of the work day would be a chief means of improving the vitality of workmen, as well as the worth of life to them.

The fatigue of workmen is largely traceable to their long work day and serves to start a vicious circle. Fatigue puts the workman in an abnormal frame of mind. He seeks to deaden his fatigue by alcohol, tobacco, exciting amusements, and excesses of various kinds. The momentary relief which he thereby obtains is purchased at the expense of an increasing susceptibility to fatigue, resulting sooner or later in complete depletion of his vital energies and in the contraction of tuberculosis or other fatal disease. The decrease in the length of the working day has not diminished the total output.

An instance in which the eight-hour day superseded the nine-hour day with entire success is the case of the Salford Iron Works, of Mather & Platt, at Manchester, England, which changed to the eight-hour day in 1893. As the firm's products were subject to keen competition in both home and foreign markets, it was obliged to look carefully after the labor cost, and its conclusion that such cost did not increase in consequence of the reduction in working hours was reached after extremely accurate comparisons by accountants, who of course took into consideration the saving in consumables, wear and tear, fuel, etc. The Bureau of Labor inquired of Messrs. Mather & Platt if they were still on the eight-hour basis, and received a reply dated May, 24, 1904, in which they stated that—

> our experience since the first year in which it (the eight-hour system) was tried has fully borne out the conclusions then arrived at, and we are fully satisfied that as regards the comparison between eight and nine hours per day the balance of advantages is in favor of the shorter period.[a]
>
> In 1894 the hours of labor of about 43,000 workmen in British government factories and workshops were reduced to forty-eight per week. Of this number, 18,600 received a reduction of five and three-fourths hours a week, and 24,300 had their time reduced two and one-half hours a week. With no change in piece rates the workmen were able to earn as much as formerly. Day workers received an increased hourly rate of pay to make their earnings per week of forty-eight hours equal to those per week of fifty-four hours. It was not found necessary to increase the number of day workers.[b]

In 1899 the owners of the great Zeiss optical goods factory at Jena, Germany, introduced the eight-hour day and then made careful records of the results. In 1903 it was announced that although the aggregate number of hours worked had decreased 15 per cent the output per hour had increased 16.2 per cent.[c]

---

[a] New York Labor Bulletin No. 25, June, 1905, p. 240.

[b] Board of Trade Labor Gazette, July, 1905, reported in New York Labor Bulletin No. 28, March, 1906.

[c] New York Labor Bulletin, No. 25, June, 1905, p. 240.

At Liege it was found in a sulphuric acid establishment similar to a foundry[a] that shortening the working day from eleven hours to ten, from ten to nine, and so on gradually down to seven and one-half, resulted, in each case, in an increase of the output.

The Solvay Process Company, of Syracuse, installed in 1892 a system of three eight-hour shifts in place of the two previous shifts of eleven and thirteen hours, respectively. It was stated by the assistant general manager in 1905 that the change had considerably lessened the wear and tear on the men, and that they could be called on to do their work at their highest state of efficiency, which had not been possible on the two-shift basis. President Hazard of the company writes:

> In general, I can say that the results of the change from a twelve-hour shift to an eight-hour shift were very satisfactory and have continued to be so. While the immediate result was to considerably increase the cost per unit of product, the efficiency of the men gradually increased, so that at the end of about one year the first increase has been overcome and the cost per unit of product fell to a point even lower than had been obtained under the twelve-hour shift, and further the time consumed per unit of product has since been so reduced that we are today and for some time have been operating with a smaller number of hours per unit of product than we had under the twelve-hour shift.

Further proof of the benefits of the change to the three-shift day is furnished by the records of the Solvay Mutual Benefit Association for 1891 and 1904. The days lost per man by sickness each year fell from seven and one-half days in 1891 to five and one-half days in 1904.

It is not maintained that in all cases productivity will be as great in eight hours as in nine. Cases to the contrary could also be cited. The point to be insisted upon is not that it is profitable to an employer to make the work day shorter, for often it is not, but to show that it is profitable to the nation and the race. Continual fatigue is inimical to national vitality, and however it may affect the commercial profits of the individual it will in the end deplete the vital resources on which national efficiency depends.

In the interests of this efficiency, a longer time at noon for lunch is usually necessary. The present economy of lunch time is shortsighted, tends to food bolting, indigestion, a drowsy and tired afternoon, and inferior work. This has been shown by actual experience.[b]

The accident bulletins of the Interstate Commerce Commission contain frequent records of disasters caused by the long hours of railway employees. In a recent bulletin, No. 27, two collisions are attributed to the mistakes of employees who have been on duty much longer than the instinct of safety should allow. Collision No. 3,[c] which killed 2 and injured 13, was due to the mistake of a station operator who had been on duty from 7 a. m. to 3.30 p. m. and who had returned to duty at 8 p. m. The collision took place at 12.30 a. m. the next morning.

SECTION 7.—*Importance of preventing undue fatigue.*

The economic waste from undue fatigue is probably much greater than the waste from serious illness. We have seen that the average serious illness per capita is usually about two weeks each year. This is about 4 per cent of the year. Expressed differently, about 4 per cent of the population is constantly sick.

On the other hand, the number that suffer partial disability through undue fatigue certainly constitute the great majority of the population. No observer can fail to conclude that this is true of the American working, business, and professional classes, and the latest word among the students of school hygiene is that it is true to a large extent even among children. If therefore we assume that only 50 per cent of the population is suffering some impairment of its best powers through undue fatigue, we are on safe ground. The extent to which the power of this supposed 50 per cent of the population is impaired must certainly exceed 10 per cent. When we consider that young men, supposed to be perfectly well, have the enormous room for improvement indicated in this chapter, and when we consider the gratifying results of experiments with a shorter work day it will be seen that the true impairment is probably several times 10 per cent. Yet if only 50 per cent of the population are suffering an impairment equal to only 10 per cent of its working powers, the result is equivalent to 5 per cent of the population suffering total impairment which is more than the 4 per cent impairment from serious illness.

The relatively slight impairment of efficiency due to overfatigue leads to more serious impairment. Just as minor ailments prove to have an unsuspected importance when considered as gateways to serious illness, so the inefficiency from fatigue is vested with great significance as the first step toward minor ailments. Obviously if overfatigue could be reduced to a minimum, this reduction would carry with it the prevention of the major part of minor ailments, which in turn would lead to a great reduction in more serious illness, and this finally would lead to a great reduction in mortality. A typical succession of events is first fatigue, then colds, then tuberculosis, then death. Prevention, to be effective, must begin at the beginning.

But prevention is merely the first step in increasing the breadth of life. Life is to be broadened not only negatively by diminishing those disabilities which now narrow it, but also positively by increasing the cultivation of vitality. Here we leave the realm of medicine and enter the realm of physical training. The first and lowest step is gymnastics. This is valuable—far more so than the ordinary sedentary man who neglects it realizes—but it is after all a kind of medicine not altogether pleasant to take and far less valuable to him who takes it than are athletic sports, which constitute the next highest stage. Beyond athletic sports in turn comes mental, moral, and spiritual culture, the highest product of health cultivation. It is an encouraging sign of the times that the ecclesiastical view of the Middle Ages, which associated saintliness with sickliness, has given way to modern "muscular Christianity," typified in Young Men's Christian Associations with their gymnastics and athletics. This is but one evidence of the tendency toward the "religion of healthymindedness" described by Professor James. Epictetus taught that no one could be the highest type of philosopher unless in exuberant health. Expressions of Emerson's and Walt Whitman's show how much their spiritual exaltation was bound up with health ideals. "Give me health and a day," said Emerson, "and I will make the pomp of emperors ridiculous." It is only when these health ideals take a deep hold that a nation can achieve its highest state of development. Any country which adopts such ideals as an integral part of its practical life philosophy may be expected to reach or even excel the development of the health-loving Greeks.

The means of securing both the negative prevention of invalidity and the positive accumulation of vitality will form the subject of Part III.

Part III.—METHODS OF CONSERVING LIFE.

CHAPTER VI.—*Conservation through heredity.*

SECTION 1.—*Heredity and environment.*

That the waste of life through preventable disease and death is enormous appears clearly from the facts already cited. The practical problem is this: If such waste is really preventable, what are the conditions necessary to make prevention an accomplished fact? There are two main conditions. First, a general desire for improvement; second, a general knowledge of how to secure that improvement.

Once the general public recognizes the needless waste of vitality, it will not be content until that waste has been eliminated. To such an awakening the American instinct of economy is in itself a powerful spur. Practical men are coming to consider it "good business" to take some care of their own vital resources. As this view gains ground, habits and fashions will adapt themselves to the change. The folly of the man who loses his health in the pursuit of wealth, and then for the rest of his days spends his wealth to win back health, is beginning to be appreciated.

Human vitality depends upon two primary conditions, heredity and hygiene, or conditions preceding birth and conditions during life. In other words, vitality is partly inherited and partly acquired.

It is well known that cultivated plants and animals have been greatly changed and developed by breeding. "The original apple, as offered by nature to mankind, was the small, sour, bitter crab of the forest, unpleasant, indigestible, innutritious. * * * In 1710 Doctor Davenant, a writer on political economy, estimated that the average weight of dressed cattle did not exceed 370 pounds. * * * In 1846 McCullock stated that 'at present the average weight of cattle is estimated at or about 800 pounds.'"[a]

Human heredity is now dependent on haphazard selection. Little attention is paid by those who contemplate marriage to the question of how much stamina will be transmitted to the next generation. The story was told of a famous dog fancier who, when asked why he paid so much attention to his dogs but delegated the care of his children to nurses, replied: "My dogs have a pedigree." Human pedigrees, no less than canine, rest on a physical basis; yet genealogical records of human beings, while they have much to say of social position, have very little to say of physical capacity or intellectual ability. Those who, like Galton and Pearson, believe in a science of eugenics, hope that the day will come when pride of inheritance will include as important, if not as the chief items, physical, mental, and moral stamina. A tendency in this direction can be discerned. When the nobility commanded the reverence of all classes, quite irrespective of ability, commoners, however well endowed by nature, could never obtain the same respect. But to-day the English House of Commons is more honored and respected than the House of Lords.

---

[a] See Dr. Edward Jarvis, Political Economy and Health, Fifth Report, Mass. Board of Health, 1874. Doctor Jarvis adds that human life is as "expansible" as animal life.

Once the importance of a physical pedigree comes to be rated at its true value, a man's pride in his own inheritance will show itself in a correlative feeling of responsibility for future generations. For the sake of children yet unborn, men and women will set for themselves physical ideals of the highest order.

SECTION 2.—*Eugenics.*

The whole question of race improvement through heredity constitutes the subject-matter of the new science of eugenics. The devotees of this science are at present engaged in studying the laws of heredity in all its aspects. The Mendelian doctrine of heredity, with the theories of Darwin and Weissman, are some of the topics which need to be studied in reference to their practical application.

Until more results have been obtained, it would be premature to make great claims for the possible future usefulness of applied eugenics. A word may be said to prevent misunderstanding as to its aims. Many have supposed that the object of eugenics was to bring about suitable marriages by compulsion of the Government. Such a proposal would not only be absolutely impracticable, but would defeat the very ends aimed at. Marriage, above all human choices, must, as a rule, be left to the individual, guided by his ideals alone. By the change of these ideals alone can the character of marriages be influenced. Sir Francis Galton, the founder of the science of eugenics, expects intelligent public opinion to be the chief guide in marriage. Just as the union of brother and sister is tabooed, and the marriage of even first cousins[a] is eyed askance—whether justly or not does not matter—so, if the aims of eugenists are carried out, an obviously unhygienic marriage will be frowned upon. It was somewhat in this way that the ancient Sparta raised its vitality to a high point of physical excellence.

Galton has pointed out[b] that present restrictive rules of marriage selection are endured without any sense of loss of privilege or freedom. For example, members of the European nobility are, in their marriage choice, restricted almost wholly to fellow-aristocrats; yet so much has this restriction become a part of their ideal and creed that the narrowness of the range of choice is not usually realized.

Even granting that some marriages are studiously calculated to win money or title, a much stronger or more pervasive, although unconscious, influence is exerted by the ideals which young men and women at marriageable age have formed of what their companions for life should be. Nothing is more certain than that if from childhood they were trained to regard vitality as the first essential in an ideal man or woman, this would influence their personal fancy. Health, beauty, and vitality are natural objects of admiration and love. Titles, wealth, and other extraneous attractions are not. To lessen the public esteem for these, and to increase the esteem for natural human merit, will tend to increase not only the number of healthy marriages, but the importance of the rôle played by normal love. If, therefore, eugenic ideals ever hold sway, love marriages will not only continue to exist, but will become more frequent. Love is a primal and natural instinct, and the more natural men and women are, and the more highly they esteem natural vitality, the more will they be guided by mutual attraction.

---

[a] In at least 20 States the marriage of first cousins is forbidden by law. An excellent discussion of this subject is contained in "Consanguineous Marriages in the American Population," by G. B. L. Arner, Ph. D., New York (Longmans), 1908.

[b] "Sociological Papers," London (Macmillan), 1906, Vol. II, p. 12.

If a considerable percentage of the population once shall come to regard vitality as an essential endowment, the effect on mating will be felt in two ways: First, a larger percentage of healthy persons will marry, leaving a larger percentage of unhealthy persons single; second, healthy persons will mate with each other, and unhealthy persons, in so far as they marry at all, will do so among themselves. Of mixed matings there will be a smaller number. Both of these results will tend gradually toward the improvement of the race. That the first—the increased proportion of marriages among the healthy—will do so, is obvious. The second—the marriage of like with like in respect to health—would, it seems probable, operate to increase the number of progeny of healthy couples and decrease that of the unhealthy, especially after the first generation.

Since athletics have come into vogue it is well known that the athletic ideal has led to athletic mating. The tendency of the present devotion to athletics must be to elevate the respect for physical prowess. The high esteem entertained in Japan for physical training and for hygiene as a guarantee of the fighting power of the country, constitutes an object lesson, if not a warning, to Americans who wish their country to be the peer of the best. It would be folly, of course, to expect any change in ideals so complete that there would not be numerous exceptions to hygienic mating, but, once the bulk of mankind are guided by a truer principle in forming marriages, the effect on racial development will make itself distinctly felt within a generation. As President Roosevelt has said: "The preservation of national vigor should be a matter of patriotism." Some persons would even make it a matter of religion.

SECTION 3.—*Eugenics and law.*

It is possible, however, that governmental interference with the birth rate may in future be employed to a limited extent. Two ways have been suggested: One is for the Government to give prizes or bounties to couples that conform to certain specified standards in the same way as the French Government has encouraged the increase of population by offering inducements to couples of the poorer class who raise seven or more children.[a]

The second is to forbid alliances among criminals, paupers, and the feeble-minded. These classes fall under the tutelage of the State, and thereby forfeit their right to free choice. Already Indiana,[a] Connecticut,[b] Michigan,[c] and other States in this country, have passed laws of this sort.

---

[a] In 1889, fathers of seven children were made exempt from payment of the personal property tax. This exemption was in 1890 limited to fathers who paid taxes of not over 10 francs each.

Indiana extends the prohibition to all persons suffering from transmissible disease of any sort. This prohibition is called into daily operation in that State. It is in the power of the Indiana state board of health to raise by degrees the standards of health demanded of those who desire license to marry, a provision that aims directly at the improvement of human vitality in the State. Indiana has gone even further and has recently provided[d] that confirmed criminals, imbeciles, idiots, and rapists, procreation by whom is deemed inadvisable by experts, shall be unsexed (or "sterilized") by surgical operation. Under this law over 800 prisoners have been sterilized to date.[e]

The experiments started in Indiana and other States will be interesting to watch, and promise an improvement over the conditions which have prevailed too often in the past. Professor Brewer, of Yale, tells of a case in Connecticut some years ago where a feeble-minded pauper woman, kept as a public ward, was admired by a half-witted farmer living in an adjoining town. A selectman of the town maintaining the woman "to get rid of her support" encouraged their marriage. His short-sightedness, even from the standpoint of immediate money economy, to say nothing of racial economy, became apparent when, a few years later, she and her husband and three idiotic children drifted into the poorhouse of the husband's town.

That laws like the ones discussed, but of gradually increasing severity, will become common in the future seems likely; and, as Professor Lankester has remarked, humanity will probably submit in the future to communal restriction of the right to multiply with as good grace as it has given up the right to rob and to rape.[f]

The effect of restrictions upon free right of marriage is discussed by Doctor Hurty, secretary of the Indiana state board of health, as follows:

> It seems most essential and necessary that we have laws for the prevention of the production of the unfit if society is to be saved from destruction. Modern hygiene, under which I include in this instance all such benevolent institutions as insane asylums and institutions for the feeble-minded, is extending the duration of life of the dependents and deficients, and it might be added that the humane and hygienic care in the prisons is extending the duration of life of the delinquents. In Indiana the life duration of the insane has been extended eight years within the last two decades. This slight extension means a very considerable burden upon the people, and if this class of deficients is unrestricted we can readily see what a burden time will place upon society. The production of the unfit must cease if charity and hygiene continue. Otherwise it seems certain that society will be swamped.

[e] Letter from Dr. J. N. Hurty.

[f] E. R. Lankester, "The Kingdom of Man," London (Constable), 1907, p. 41. The recent report of the Royal Commission on the Care and Control of the Feeble Minded recommends such restriction.

While institutional treatment of the insane is right and proper from a humanitarian point of view, by bringing an increase in the average insane lifetime it adds to the public burden and enlarges the figures of the living insane. Mr. Sanborn estimates the average insane life in Massachusetts at thirteen years, of which at least three years occur, on the average, before hospital treatment is applied. He adds:

> I suspect we have come nearer to statistical accuracy on this question in Massachusetts than has been reached in any region of equal population anywhere. The world has been gradually coming round to the conclusions reached by the late Dr. Pliny Earle (of Northampton) and myself, viz, that the changes in the social and sanitary conditions of all civilized countries have increased the number (proportioned to population) of new cases of insanity, while the improved treatment of patients in the meantime has made the average insane life longer than formerly, and that in spite of the well-known increase in forms, like paresis and epilepsy, which may soon end fatally.

Interesting records exist of two families of criminals, the so-called "Jukes" and the "Tribe of Ishmael." From the one man who founded the "Juke" family came 1,200 descendants in seventy-five years; out of these, 310 were professional paupers, who spent an aggregate of two thousand three hundred years in poorhouses, 50 were prostitutes, 7 murderers, 60 habitual thieves, and 130 common criminals.

Dugdale[a] has estimated that the "Juke" family was an economic loss to the State, measured in terms of potential usefulness wasted, costs of prosecution, expenses of maintenance in jail, hospital, and asylums, and of private loss through thefts and robberies of $1,300,000 in seventy-five years, or over $1,000 for each member of the family.

Similarly, the "Tribe of Ishmael," numbering 1,692 individuals in six generations, has produced 121 known prostitutes and has bred hundreds of petty thieves, vagrants, and murderers. The history of the tribe is a swiftly moving picture of social degeneration and gross parasitism, extending from its seventeenth-century convict ancestry to the present-day horde of wandering and criminal descendants.[b]

Had the original criminals in the "Juke" family and the "Tribe of Ishmael" been sterilized under some law like that of Indiana, this country would not only have been spared a widely disseminated criminal, epileptic, and immoral strain, but would have saved hundreds of thousands of dollars paid out for criminal suits and for institutional care, to say nothing of the expenses still to come from the incapacity and criminality of future generations.

These cases present only one side of the case. Over against them may be set illustrious families in which great intellectual ability and moral worth have been passed on through many generations. Such a one is the Hohenzollern family. In commenting on the frequent occurrence of persons of surpassing mental and moral attainments in this family, Woods[c] says: "It is particularly suggestive of what might be done with the human race were mankind ever so inclined." A similar example from a different walk in life is afforded by the Darwin family, where for four generations in direct line (Erasmus, Charles,

George, Horace, and Francis) as well as in collateral lines (e. g., Frances Galton) scientific ability of the first rank has been manifest.[a]

President Roosevelt has pointed out that "race suicide" is a sign and accompaniment of coming decay. Mere numerical increase is not the whole solution, however; there must be improvement in quality also. A race that can not hold its fiber strong and true deserves to suffer extinction through race suicide. The decline of our Puritan stock, so well pictured in the genteel but worn-out Pyncheon family of Hawthorne's novel, need not alarm us if we can replace it with a new influx from the West or from the vigorous stocks of Europe.

There is one problem which concerns both the numbers and the quality of future generations, which hitherto has received practically no attention except in a partial report upon the subject in Australia. This problem is, What is now and will be the effect of voluntary childlessness upon the size and character of the birth rate and upon morals? It would be useless, here, however, to do more than mention this as one of the gravest problems in the world to-day. Ronald M. Byrnes[b] shows that the fecundity of Yale graduates has steadily diminished from 5.7 for the graduates of 1701–1791 to 2.0 for those of 1867–1886. This reduction is much greater than the reduction for the whole country, which is reported by the census to be from 5.8 in 1790 to 4.6 in 1900. Degenerates have large families. From a study of 150 degenerate families, Doctor Tredgold[c] found that the average number of children per family was 7.3, while the normal average for the country at large (England) is 4. These figures do not specify the frequency of marriage among degenerates or the mortality. Unless the one is sufficiently low and the other sufficiently high, there must follow deterioration. General reduction of the birth rate may end in depopulation. It is not unlikely that this phenomenon will be the stimulus needed to bring about practical eugenic reforms.

What eugenics might possibly accomplish is indicated by one writer in the following manner: "How rapidly the race would advance if mankind should resolve: 'The next generation must be born with healthy bodies; must be nurtured in healthy physical and moral environments; and must be filled with the ambition to again give birth to a still healthier, still nobler, generation.' "[d]

CHAPTER VII.—*Conservation through public hygiene.*

SECTION 1.—*Municipal hygiene.*

Whatever improvements in heredity may sometime be achieved, the benefits of their influence can be enjoyed only by future, perhaps distantly future, generations. We of the present generation have to take our heredity as we find it. We can not follow the advice of the humorous philosopher to begin life by selecting our grandparents; but, through hygiene, we can make the most of our inherited endowment. Even such a limited effort offers large—amazingly large—rewards.

Ideal conditions for health comprise a pure and disease-free atmosphere in which to live and work; pure food and a pure water supply; protection from infection and accident; and a proper adjustment of work, rest, and amusement. Existing conditions are not only far from ideal, but also far from what might easily and speedily be attained.

That the saving power of hygiene is great is now universally recognized; that it will be greater is the hope and belief of those most competent to judge. "If hygiene were able to prolong life when it was little developed, as was the case until recently, we may well believe that, with our greater knowledge of to-day, a much better result will be obtained."[a]

There is every reason to believe that human beings are as amenable to cultivation as other animals and plants. Professor Graves, of the Yale Forest School, states that by protecting trees from infection their lives may often be prolonged a century. Domestic animals are equally dependent on care. Doctor McGee states that the growth of a colt may be stopped by giving it alcohol.

The methods of securing improvement in health conditions may be roughly classified under three groups: Public hygiene, semipublic hygiene, and personal hygiene. The first group refers to activities of the government; the second refers to activities of the medical profession and institutions such as hospitals, sanatoria, schools, and factories, and to voluntary associations; the third group deals with the private life of the family and the individual. Each of these three groups covers phases of all three branches of hygiene, viz, the hygiene of environment, nutrition, and activity.[b]

In this chapter we have to deal with public or governmental hygiene. This branch has been chiefly concerned with pure air and pure food and with organisms producing epidemic diseases. Boards of health are a recent invention, and in this country they have as yet been only imperfectly developed. They can never become the power they should be until, first, public opinion better realizes their usefulness and the fact that their cost to the taxpayer is saved many times over by the prevention of death and disease; second, more and better health legislation is enacted—national, state, and municipal; and, third, special training is secured for what is really a new profession, that of public health officer—a profession already recognized in England by a special diploma.

---

[a] Metchnikoff, Prolongation of Life, p. 144.

[b] Since this report was written there has appeared the excellent and inspiring "Civics and Health," by William H. Allen, Bureau of Municipal Research, New York (Ginn), 1909.

The health officer should be supported entirely by the salary of his office and should be absolutely prohibited from practicing medicine. Not only are his duties incompatible with practice quite as much as those of judges with the practice of law, but if he gives them proper attention there is no time for other duties. No court, police, or fire department, or other agency of government, can be more important to a people than this under the complex conditions incident to the rapid growth of both rural and urban populations. It is so important that this be realized that it is worthy of serious consideration as to whether it would not be better for all imperfectly equipped and supported health boards in this country to resign—so that the authorities and people would be brought face to face with the knowledge that they have no real protection except in the emergency of an epidemic—than for existing conditions to continue.

Laboratories, research workers, statisticians, and other facilities for the performance of a national board of health's duties should be furnished in proportion to the power and wealth of the Government and the vast interests it would protect and promote. The results of its scientific and collective investigations should be constantly utilized in promoting health in the army and navy, in protecting streams and soils from pollution, in the construction of interstate waterways, in the reclamation of swamp lands, and in other public works involving health problems of supreme importance to the future of this country.[a]

Public hygiene may be studied under three heads, corresponding to our governmental divisions: Municipal hygiene, state hygiene, and federal hygiene.

Municipal hygiene and sanitation are placed largely in the hands of city boards of health, or equivalent organizations, which have power to issue sanitary regulations, abate nuisances, and even to punish infractions of their instructions by fine and imprisonment. Sanitary legislation is a product of advanced civilization. To-day not a city is without a board of health. The powers of these boards have grown, till to-day they are by no means inconsiderable; yet they must be given even greater authority, if our municipal sanitary conditions are to be what they should. Public apathy and political interference are such that health authorities can not enforce their orders. In addition to the acquirement of greater power, city health boards often need purification of motive and the banishment of political bickerings and personal jealousies.

The simplest ordinances along the line of public hygiene are those against spitting, which now remain so largely unenforced.

The smoke nuisance is another seemingly simple form of air vitiation that is receiving attention to-day. Sulphuric acid is apparently the most injurious factor. The corrosion of stone structures suggests the irritation resulting in catarrh and other respiratory mucous-membrane troubles.[b]

The effect of the introduction of closed sewers on the reduction of tuberculosis should not be overlooked. By closing sewers, impure gases have been confined, thereby removing an important source of air pollution. Some cities realize that pure air spells life and health to its inhabitants, and that pure air is a possibility only when atmospheric particles of soot and dirt are removed.

Regulations governing garbage removal, notification and isolation of disease, and the like are as a rule enforced, and new regulations are being issued constantly. Substantial progress is shown each year in the purification of city water supplies, in the improvement of sewage disposal, and in the bettering of drainage conditions. Streets are more thoroughly cleaned and the elimination of public and private nuisances continues without ceasing.

---

[a] Letter from Dr. J. N. McCormack.

[b] See Journal American Medical Association, September 7, 1907, p. 813.

Our city streets have received greater care since Colonel Waring organized his "white wings" brigade in New York City a dozen years ago, thus proving the great effectiveness of clean streets in the elimination of disease. The probable elimination of the horse from our city life, through automobiles, the betterment of our trolley systems, and the introduction of subways (especially freight subways) will go far to improve our city atmosphere. The problem of city air will be half solved when our streets reach their proper state of cleanliness. The gradual elimination of the horse will tend not only to produce cleaner air, but also to reduce the dangers from flies. It is in horse manure that the common horsefly ("typhoid fly") chiefly breeds. Doctor Howard attributes the termination of typhoid in certain parts of Washington to the displacement of the horse by the automobile.

Only within a dozen years has the dread importance of insect carriers of disease been realized. That mosquitoes carry malarial germs; that flies are the propagators of typhoid, cholera, and other infectious diseases; that rats breed the fleas which transmit to man the dreaded Asiatic plague [a]—all this knowledge is of recent origin.[b]

Well people are sometimes carriers and distribute typhoid, diphtheria, etc., a fact which complicates public-health regulations.

The simple reporting of all contagious disease to the health authorities immediately on its appearance is often the means of preventing an epidemic.

Smallpox epidemics are prevented both by quarantine and vaccination. Because of the outcry against compulsory vaccination, in some places the responsibility for vaccination is being thrown upon the individual. This is true in Leicester, England, and in Minnesota. Doctor Bracken, secretary of the Minnesota State Board of Health, writes that since the quarantine has been abandoned and the individual has had the option of being vaccinated or not, a larger number has been vaccinated and smallpox has diminished.

We are awaking to the importance of securing for ourselves, through our city health agencies, a pure milk supply. Great danger is also present in cream, butter, cheese, and ice cream. More than one city has inaugurated a policy of careful supervision of the milk supply. Montclair, N. J., has a well-considered plan in operation whereby the bacterial count of each dairy is public to inquirers at the board of health. This species of publicity will some day prove a strong incentive to a better milk supply. Some cities have even established municipal stations, where during the summer season sanitary milk may be purchased at cost. Doctor Goler, of Rochester, has emphasized the fact that "We employ physicians to cure children affected by the diarrheal diseases from dirty milk, while we permit the sale of dirty milk from filthy cattle."[a]

---

[a] See Rupert Blue, "The prophylaxis and eradication of plague," California State Journal of Medicine, Vol. V, 1907, p. 304.

[b] A full treatment of the subject of insect-borne disease has been prepared by Dr. L. O. Howard, Chief of the Bureau of Entomology of the Department of Agriculture, for the National Conservation Commission. See also Charles Harrington, M. D., "Practical Hygiene," Third Edition, Philadelphia, (Lea), 1905, pp. 637-660.

In Rochester, through the efforts of Doctors Goler and Roby, a few municipal milk stations were established in 1897, where during July and August milk in nursing bottles could be bought at a low price. The reduction in the Rochester infant death rate between 1897 and 1906 is doubtless due to many other conditions than the quality of milk; but the special attention drawn to the milk supply and the consequent education of the public, which probably boiled its milk when it could not get it clean, would explain a considerable part of the reduction.[b]

The interrelation of the purity of milk supply and infant mortality is shown by the following excerpt from Doctor Woodward's annual report as health officer of the District of Columbia for the year 1907:

> High as is the infantile mortality even now from diarrhea and inflammation of the bowels, it is far below the figures that formerly prevailed.
>
> The only explanation for the fall in the death rate from infantile diarrhea that I have been able to discover is the enactment on March 2, 1895, of the law regulating the sale of milk in this District and the establishment of dairy and dairy-farm inspection under the provision of that law.

The weekly report of the Cincinnati board of health for August 21, 1908, states:

> As far as we know, there has been but one death among the babies whose food supply has been obtained from the milk stations. When it is taken into consideration the large number of children we have supplied, this statement is certainly a fitting commentary upon the value of a bacteria-free and chemically pure milk.

At the recent International Congress on Tuberculosis, one delegate reported an experiment in England which has not yet appeared in print. In Liverpool the local government board tried the experiment of using pasteurized milk. The amount of illness and death in that city from children's tuberculosis is very great, yet among 1,800 children who were given pasteurized milk and who were carefully watched every week not a single case of tuberculosis developed, which seems to prove conclusively that children's tuberculosis is entirely preventable by the use of pure or pasteurized milk. This is interesting, though at variance with former opinion regarding bovine tuberculosis in children.

In this section should also be mentioned such municipal health agencies as public baths, bacteriological laboratories, and the distribution and administration of specific antitoxin, vaccine, and free medical service. Municipal inspection of local abbatoirs is also important, inasmuch as federal inspection covers only establishments engaged in interstate business.

Most important of all is the matter of preventing pollution of the water supply of cities, a topic that will receive fuller treatment later in the chapter.

---

[a] See George W. Goler, M. D., "Municipal regulations of the milk supply," paper at the meeting of the American Medical Association, 1907, p. 2. For conclusions based on a study of 330 milk-borne epidemics, see George M. Kober, M. D., "Milk in relation to public health," S. Doc. No. 441, Government Printing Office, 1902.

[b] See George W. Goler, M. D., "Origin, development, and results of municipal milk work in Rochester, N. Y.," Maryland Medical Journal, June, 1906.

The needs of municipal as of state hygiene are not so much new laws as better men to enforce existing laws and an aroused public opinion that will result in the appropriation of funds sufficient to enable health authorities to perform their duties in an efficient manner. Larger appropriations will doubtless bring better men into the public-health service.

SECTION 2.—*State hygiene.*

State hygiene is necessary to supplement municipal hygiene for many reasons. One is that the country often has no other sort of sanitation possible. Another is that the city is dependent on the country for its water, milk, and other supplies. Dr. W. G. Daggett, of New Haven, has emphasized the fact that in origin typhoid is largely a rural disease and must be combated by controlling rural privies and other sources of infection.[a] A competent authority asserts that "old country wells, so much valued by their owners, are a positive menace to public health. Fully 50 per cent of these are unfit for use." Much of the typhoid fever brought by milk is readily traceable to such wells.

In the control of the liquor traffic the State and local units should cooperate.[b]

A state, rather than a municipal, function is the regulation of woman labor and child labor. The growth of public opinion on this point has been rapid. In order to make the working hours meet the physiological requirements of women, two special conditions should be attended to. One is her monthly period; the other is childbearing. The neglect of both is responsible not only for physical impairment of factory women, but also for their inability to perform their functions as mothers of the race. Doctor Stiles, of the Public Health and Marine-Hospital Service, has suggested a very sensible remedy to meet the first of these conditions, and one which has met with the approval of many factory employers. It is that each woman shall have the right, once every month, to walk out of the factory without any questions being asked, and without loss of the day's wages. The matter is further simplified in factories provided with a matron and a rest room. In respect to the second condition—that of childbearing—the evidence is clear and convincing. Women, on account of their imperfectly developed muscular system and more delicate physique, are unfitted for hard work; nor should they be obliged to work steadily in a sedentary position, especially at the sewing machine, or other occupations involving the use of the lower extremities. Special protection should be extended to them during the childbearing period. It is a matter of constant observation that women who have to deny themselves proper rest and care during the next six weeks after confinement are very liable to suffer from hemorrhages and chronic uterine diseases, while miscarriages and premature births are not infrequent results of overwork.[c]

[b] See "Regulation of the liquor traffic," Annals American Academy of Political and Social Science, November, 1908.

[c] George M. Kober, M. D., "Industrial and personal hygiene," "Report of Committee on Social Betterment of the President's Homes Commission," Washington, 1908, pp. 67–68.

The employment of mothers shortly before and after the time of childbirth is prohibited in a number of European countries. American statutes, however, are almost silent on the question.[a] Professor Jevons went so far as to advocate the enactment of legislation forbidding the employment of mothers till their youngest children were at least 3 years old.

The beneficial effect on the mother, and especially on the child, of forbidding the factory to her just before and after childbirth has been proved many times. The case of M. Dollfus, a large employer of women at Mulhausen, in Alsace, has been repeatedly cited. He required mothers to remain away from their work for a period of six weeks after childbirth, during which time he paid them full wages. The decrease in infantile mortality in the first year of the experiment was from more than 40 to less than 18 per cent.[b]

The waste of vitality from unphysiological hours of work is most striking in the case of children. It is hardly to be questioned that children need longer hours of rest and sleep than adults, and that their immature bodies are much closer to the fatigue limit. A little girl in a southern mill replied to Mrs. Van Vorst's query whether she were often tired, "Why, I'm always tired." Except in unusual cases and for limited periods, child factory labor can not be defended on any hygienic grounds. The period of preparation for a wholesome, healthy life should be left free from the cares and evil physical influences of factory life. No child should run the risk of serious accident, deformity, dwarfing, or mental stunting through factory labor. It is true that in the South child labor is often the lesser of two evils, the other being the life on a farm where, through soil pollution, the child contracts hook-worm disease. Here the abolition of child labor should be preceded by the abolition of hook-worm disease.[c]

Closely connected with the restriction of child and woman labor is factory legislation in general, dealing with hours of labor, factory hygiene and sanitation, and dangers from industrial accident.

The hours of labor have for a century been on a gradual decrease. A hundred years ago fourteen and fifteen hours were by no means uncommon. The first public action regarding hours of labor was taken by President Van Buren in 1840, when he set ten hours as the limit of the working day in all government establishments. Thirty years later this was lowered by Congress to eight hours. Since 1850 the fight has been waged for a shorter day, both by labor unions and individuals; and the statutes of nearly all States contain legislation limiting the working hours of women and children in all industries, as well as of all workers in certain industries, especially mining, railroading, and the more dangerous manufacturing industries. The Aldrich report of 1890[d] estimated that the American working day averaged eleven and four-tenths hours in 1840 and ten hours in 1890. Tables based upon annual reports of the Bureau of Labor show a reduction of about 4 per cent from 1890 to 1903,[e] while it is the opinion of United States Commissioner of Labor Neill that the figures for 1908 would unquestionably be lower than for 1903, as the struggle for the shorter working day has been making steady progress each year.[a]

[e] T. S. Adams and Helen L. Sumner, "Labor Problems," New York (Macmillan), 1905, pp. 516–518.

The frightful losses of life and efficiency from preventable accidents can be prevented only by state legislation.[b]

Our employer's liability acts are very unsatisfactory, because they fix no scale of compensation for injuries, but necessitate expensive lawsuits to determine in each case the sum due. A president of an insurance company doing a large business in employer's liability insurance states that of the sums they pay employers only one-quarter reaches the injured employee, who is forced to spend the other three-fourths in litigation. In England the workman's compensation acts have substituted a system of specific sums for which the employer is liable. Not only does this result in larger indemnities reaching the injured, because suits are ordinarily unnecessary, but it has the further beneficial effect of reducing the number of accidents by inducing employers to instal safety devices.

The regulation not only of the place of work, but also of the dwelling place, has come to demand action on the part of the State as well as of the community. The growth in tenement-house legislation during the past ten years has been most encouraging. Standards of sanitation for our large buildings have been raised; provision is increasingly made for good light, air, water, and for protection from fire; and the "rookeries" of old are giving way to improved tenements. Yet New York City still contains 300,000 rooms without a window.[c]

SECTION 3.—*Federal hygiene.*

The regulation of disease has increasingly become a national function. The exclusion of immigrants with infectious diseases is only one instance of this; another is the work of our Public Health and Marine-Hospital Service, which not only regulates the spread of disease from State to State, and regulates by quarantine the entry of disease from without the country, but also assists local health boards in their fights against epidemics and disease scourges. Epecially is this true in coastal cities. The Marine-Hospital Service assisted New Orleans to eliminate yellow fever and San Francisco to rid itself of bubonic plague. In addition, this service treats 50,000 seamen of the merchant marine each year, conducts a large number of hospitals and relief stations, examines pilots, life-saving crews and revenue-service men, and conducts a well-equipped hygienic laboratory.

Federal, state, and municipal sanitation are all concerned with the hygiene of transportation. To-day almost the whole American public travels, and it is therefore most important that the conveyances which they occupy, whether carriage, cab, street car, or railway train, shall be sanitary in respect to ventilation, cleanliness, toilet facilities, spittoons, dust, smoke, sleeping-car accommodations, and the like. In smoking cars, in addition to the smoke itself, the floors are usually befouled with tobacco juice and other expectoration. The efficient remedy here as elsewhere is to be found, not simply in providing facilities for cleanliness, but in fostering the present public sentiment against spitting and other untidy habits. A physician of experience maintains the opinion that "foul air in railway trains and street cars is the cause of serious poisonings called 'colds' and 'grip,' particularly in those many trains where air from the smoker sweeps through passenger cars."

---

[a] See Bulletin of the Bureau of Labor, No. 77, July, 1908, pp. 6–7; also, "First Annual Report on Changes in Rates of Wages and Hours of Labor in Massachusetts," Boston, 1908, pp. 592–3.

[b] The Federal Government can of course reach interstate railways. A law passed during the last session provided for a safe locomotive ash pan. Previous laws provide for automatic couplers, air brakes, etc.

[c] A. Jacobi, M. D., "The physical cost of women's work," Charities, February 2, 1907.

The development of our national quarantine methods is indicated in the following paragraph from Surgeon-General Wyman, of the Public Health and Marine-Hospital Service:

> Until 1893 there was, properly speaking, no national system of quarantine. The colonies had their own quarantine regulations before the formation of the Union, and from that event to 1893 quarantine was left to the care of state governments and by the latter to county governments or to municipalities, as the case might be. There was, indeed, national legislation, but all the acts of Congress up to 1893 relating to quarantine specially provided that the said national measures were in aid of the state and local authorities. Whatever opinions may have been held by members of the national legislature, quarantine was permitted to be exercised by the States as a police function, and even in the present law, which gives national supremacy, it is provided that assistance shall be given the States or municipalities by the government authorities, the supremacy of the latter being asserted only when the state or local authorities fail or refuse to enforce the uniform national regulations.[a]

To-day efficient inspection at our various ports of entry and at disembarking stations abroad keeps out many cases of disease each year, while the quarantine cordon thrown around ports or municipal quarters affected by infectious disease is an important factor in stamping out such disease.

Federal meat inspection chiefly benefits the foreigner, but the administration of the pure-food laws is of value to our own people.

There are two functions of Federal Government which now are very imperfectly served and which might be made of paramount importance. They are the functions of research and of the dissemination of information. A poultry raiser, or a cattleman, or a farmer can secure scientific information to guide him in his selections of fowl, or stock, or seed by applying to the Government at Washington, but information on how to raise children has up to this time been neglected by our Government. Nothing is to-day more significant of future progress than the fact that the President, the President-elect, and many Congressmen are so strongly in favor of a greater federal organization of health. Through the dissemination of information throughout the country, through enactment and administration of effective regulations concerning pure food, inspection of meat, and exclusion of foreign diseases, through research, statistics, and through better standards for state and municipal health service, a great economy of national vitality can be effected. Washington, our national capital, might be made by the Federal Government a model city of healthfulness, as a preliminary to its becoming a model in every other way.

---

Army hygiene in time of war is most important. The lack of such hygiene has shown grave consequences. In the Boer war the British army in South Africa lost more men from typhoid fever than from wounds received in battle.[a]

The efficiency of Japanese hygiene manifests itself in the fact that General Oku's army of 75,000 during the recent Russo-Japanese war had but 187 typhoid fever cases in a seven months' active campaign.

The Japanese reduced their dysentery cases from 12,052 in the Chinese war to 6,624 in the Russian war; their cholera cases from 7,667 to none; and their malaria cases from 41,734 to 1,257. This was in spite of the fact that their army in the Russian war was three times the size of that employed in the Chinese war.[b]

The crying need of better statistics is trenchantly expressed by Dr. Cressy L. Wilbur, Chief of the Division of Vital Statistics of the Census Bureau, whose words should be read and pondered by everyone who desires to see any intelligent conservation of our vital resources:

> Sound vital statistics are the indispensable basis of modern sanitation. A nation that does not consider it necessary, or that is not able, to provide adequate means for registering the births of its own children, or for officially recording the deaths of its citizens, can hardly be supposed to attach sufficient value to human life to enable sanitary measures for its conservation to be adequately carried out.
>
> For the continental United States in 1907 somewhat less than one-half of the total population (48.8 per cent) was represented in the registration area from which returns of deaths were received by the Bureau of the Census. For the remaining 51.2 per cent of the total population of the United States, estimated at 43,774,724 persons, either very imperfect laws were in effect, giving only partial registration, quite worthless for statistical purposes, or else the conditions in many States might be represented by the statement made by one of their health officers, that it buries its dead people with no more ceremony than it buries its dead dogs.
>
> As for the registration of births, a measure which is so supremely important for the knowledge of infant mortality, for the protection of infant life, and for securing the legal rights of children, not a single State in the Union nor a single city of any considerable size makes positive claim that it registers as many as nine births out of every ten that occur. Even the city of Washington, whose law for this purpose is a direct enactment of Congress, does not arise above this low limit of efficiency. The total number of births must be known before one can make a computation of infant mortality which will be comparable with the rates given in the vital statistics of all civilized nations except the United States. This ratio depends upon the comparison of deaths of infants under 1 year of age with total births, and, as we have no exact registration of births, we can not present these important statistics.
>
> In the consideration of the effect of such an important disease as tuberculosis upon the people of the United States there is no means of knowing, within a very wide margin of error, exactly how many persons die from this cause in this country during any year. We have registration of deaths for about one-half of the population only, and the very dissimilar conditions of life and the large proportion of colored population in the unregistered half seriously interfere with any attempts to guess at the exact number. Estimates have varied from 138,000 to 200,000. The truth probably lies somewhere between them, but we certainly ought to have an exact record of the facts and not be obliged to depend upon mere guesswork in entering upon an important sanitary undertaking, such as the prevention of tuberculosis.

---

[a] Ditman, loc. cit., p. 17.

[b] L. L. Seaman, "The Real Triumph of Japan," New York (Appleton), 1906, pp. 106–7.

On the question of army diet, see Blackham: British Medical Journal, 1908, August 8, p. 311.

We are laboring, in conjunction with the American Medical Association, the American Public Health Association, and with the sanitary officials of as many States as we can interest, to extend the registration area as rapidly as possible. Ohio has just adopted an excellent law, which takes effect next year. Not a single State in the South has yet succeeded in reaching a satisfactory standard—not one of them in fact has even passed an adequate law. We are depending upon the voluntary cooperation of the States. The Government has no power, it would seem, to collect the statistics or to secure the proper registration of births and deaths by its direct action. If all of the important interests involved could be awakened to the importance of this matter, if Congress would take a direct interest in the accomplishment of this work, we could secure fairly complete registration of deaths for the United States within the next ten years.[a]

CHAPTER VIII.—*Conservation through semipublic hygiene.*

SECTION 1.—*Medical research and instruction.*

By semipublic hygiene is meant hygiene through nongovernmental institutions, including institutions for medical research, the medical profession, hospitals, sanatoria, associations, schools, and factories.

Medical discoveries have usually been made in the laboratories of medical schools, universities, and research institutions. The practical value of these institutions is only beginning to be appreciated. The benefits already received from them are great, and the benefits to come will be incomparably greater. One of the earliest medical laboratories, the Pasteur Institute of Paris, has done splendid work during the past two decades in the study of harmful and beneficent bacteria. Of more recent origin are the British Sanitary Institute in London, the Rockefeller Institute for Medical Research, the Memorial Institute for Infectious Diseases at Chicago, and the Nutrition Research Laboratory in Boston, under the Carnegie Institute of Washington. The recent achievement of Dr. Simon Flexner in finding a serum for the treatment of meningitis is but one example of what well-directed research under the auspices of such institutions can accomplish. The crowning achievement of science in the present century should be, and probably will be, the discovery of practical methods of making human life healthier, longer, and happier than heretofore.

The medical schools in this country number 156. They are rapidly advancing, although the great majority are still ill equipped for providing intending practitioners with the most recent and useful knowledge. The future practice of medicine depends more on the character and aims of the medical schools of to-day than on any other factor. At the dedication of the Harvard medical buildings in 1906, President Eliot laid down as the primary duties of that school the study of the prevention of disease and the education of the public. The need of such a school especially devoted to prevention has been fully discussed by Doctor Ditman.[b] Several universities have courses, or are taking steps to give courses in the fields not only of public hygiene and preventive medicine, but also of personal hygiene and home economics.

---

[a] Letter from Dr. Cressy L. Wilbur. See also Irving Fisher, "Mortality statistics of the United States census," publication of the American Economic Association, 1899; and R. Dudfield, "A critical examination of the methods of recording and publishing statistical data bearing on public health," Journal of the (Royal) Statistical Society, March, 1905.

[b] See N. E. Ditman, M. D., "Education and its economic value in the field of preventive medicine," Columbia University Press, Vol. X, supp. to No. 3, June, 1908.

One difficulty in establishing such a school is the lack of students who can afford the means or the time to attend. This was the experience of the George Washington University, in Washington, when a course of this kind was offered. For this reason it is gratifying to see that an effort is being made to throw open the research laboratory of the Public Health and Marine-Hospital Service for the use of health officers detailed from their several States and municipalities. In England the degree of D. P. H. (diploma in public health) is given those who meet the high standard set there for health officers.

During the last few years the American Medical Association has been seeking to study, classify, and improve the medical schools in the United States. A large committee, of which the writer is one member, has been appointed by the association to consider methods of securing such improvements as are deemed necessary. It includes in its scope the important but heretofore little appreciated field of medical economics.

SECTION 2.—*The medical profession.*

We come next to the part played by physicians, so far as relates to their "private practice." Their work as public health officers has already been mentioned, and does not concern us here. Their work in the home is of primary importance. It is on the physician that the average man relies for protection when he finds himself in the dread grip of disease.

Private practice comprises two main divisions, surgery and general practice. The first important application of the knowledge of germs was to surgery. Antiseptic surgery, originated by Lord Lister, has resulted in the saving of untold thousands of lives and has led in turn to aseptic surgery, which is still more effective. Not only has it reduced the previous mortality from operations, but it has vastly increased the number and kind of operations which can be performed in cases which under the old régime would necessarily have proved fatal.

Of one of the most recent advances the eminent surgeon Dr. W. J. Mayo writes:

> Second only to the germ theory has been the usefulness of the great discovery of Röntgen and the application of the X-ray to surgical diagnosis. It makes certain the diagnosis in a large number of conditions which were previously a matter of speculation, and enables remedial surgical measures at an early date, lessening mortality and morbidity.
>
> Another great surgical discovery is the suture of blood vessels evidenced by the work of Carrel. Its possibilities are astounding. The ability to transplant the kidney of one dog to another and have it continue its function, the amputation of a leg and its resuture, opens up the whole question of the transplantation of sound for diseased organs, especially organs which are double.[a]

In these and other surgical work a certain amount of vivisection is necessary. The present outcry against vivisection is an example of a defective sense of proportion. While needless cruelty should be avoided, the suffering of animals through vivisection, including all cases where the practice has been abused, is as nothing compared with the suffering of human beings which would be caused if all vivisection were abolished.

---

[a] Letter from Dr. William J. Mayo.

The progress of antisepsis has so reformed midwifery that puerperal fever, a former scourge of humanity, is now extremely rare. In many cases the child, by being freed from gonorrheal contamination by the mother at birth, has been saved from blindness.[a]

The advance of surgery is shown by the following table of mortality of the wounded in the wars of the nineteenth century. Antiseptic surgery was introduced at the time of the Franco-Prussian war in 1870–1:

	Per cent.
Crimean war, English troops	15.2
French troops in Italy, 1859–60	17.4
German army, 1870–71	11.1
Spanish-American, 1898	6.6
Transvaal, 1900–1901	5.5

In general practice progress is also being made. The use of violent drugs is fast going out of fashion. The recognition of the self-limiting character of most of the acute diseases sounded the death knell of the harsh drugging of the olden time. Laboratory experimentation and careful study as to the physiologic and therapeutic effects of drugs have shown the necessity of subjecting everything material or immaterial, intended for the relief of human ailments, to the crucible of the most rigid scientific scrutiny. This sentiment has grown until in the best medical circles it is properly considered a reproach for a physician to use any preparation without an exact knowledge of its composition and a definite conception of the results expected from its administration. The number of medicines used by physicians is decreasing and will, if the predictions of experts in this field may be trusted, ultimately be reduced to a small fraction of the present pharmacopœia. Many medicines, like quinine and mercury, will of course merit a continuance of use. Syphilis, malaria, hookworm disease, and some other diseases are best combated by drugs.

Serum therapy, although in its infancy as to most diseases, has opened up a field of great promise. For example, antidiphtheretic serum, the one best understood and in most common use, has reduced the mortality in that disease from 50 or 60 to 12 or 14 per cent.[b] Not so much medicines or serums, but hygiene, will probably be the dependence of the next generation of physicians. Possibly the term "medicine" will some day be almost as inappropriate in describing the treatment toward which physicians are tending as the term "leech" now is in describing the physician. The profession has ceased to be hostile to hygienic treatment, and is slowly but surely substituting it for much of the internal treatment formerly employed. The new treatment includes the use of air, light, water, food, rest, massage, mechanical vibration, electricity, exercise, and suggestion, under the names of aerotherapy, hydrotherapy, psychotherapy, etc. These remedies have the great advantage of preventing as well as curing disease.

It only remains for all medical schools and the courses of lectures now gratuitously provided by the American Medical Association for all county medical societies to teach these things in such a thorough and practical way as will reach the whole profession and bring these benefactions to the whole people. In proportion as prevention is more important than cure, the rapid advance in the knowledge and practice of preventive medicine will be of value.

---

[a] Elie Metchnikoff, "The Nature of Man," New York (Putnam), 1903, p. 210.
[b] Metchnikoff, "The Nature of Man," p. 212.

"To hygiene belongs without a doubt the place of honor in modern medicine. It is in the prevention of infectious diseases that the interest of the medical art is now mainly centered."[a] The best men are turning to these physiologic methods with enthusiasm.[b] They are learning to take into account the anxiety and other mental reactions of the patient as to what is said in his presence.[c] They are becoming more public-spirited and cooperative,[d] and alive to their responsibility to set patients a good example in living hygienic lives.[e]

The trend toward prevention is indicated in various ways—by the fact, for instance, that some physicians are now employed by families, schools, firms, associations, etc., for the purpose chiefly of preventing rather than curing disease. Women dentists graduating from the University of Michigan have made a practice of attending to children's teeth at a stated amount per month. Employers are increasingly securing the services of competent physicians to care for the health and physical welfare of their employees. This is a preventive measure, and has been found to be a "paying proposition" to the employer because of the resulting enlarged efficiency of the workers.

Their modern fight against tuberculosis has led physicians to a larger use of fresh air in their practice. At first many employed this agent merely as a "specific for tuberculosis," but its utility in all chronic ailments, such as neurasthenia, for instance, was next recognized. Latterly, fresh air has been discovered to be of use in pneumonia and other acute diseases. It is now not unusual to find physicians advising their patients, whether ill or well, to sleep out of doors. There can be no question that man was originally an outdoor animal.

The discovery of the germ origin of Asiatic cholera, tuberculosis, diphtheria, typhoid fever, bubonic plague, influenza, and other diseases, and of the part played by water, impure food, insects, rodents, and other common and almost omnipresent, but hitherto unrecognized, agencies as carriers of disease to man and animals, has awakened a world-wide interest in these subjects which, properly fostered and directed, opens up ever extending possibilities to the humanitarian, the economist, the statesman, and, still more, to the people at large.

The consequence must be a great revolution in medicine in the immediate future. The practice of medicine is destined to become a much more powerful agent than ever before in the suppression and prevention of disease. This result will be reached when the change now going on permeates the rank and file of the profession. It would be a pity if, through undue conservatism of some of its members, the profession should lose some of its prestige hard won during the last generation. Already the ever-present quack is pressing into the inviting field. As the public demands "drugless treatment" and many physicians fail to see and meet that demand so far as it is rational, the quacks see their opportunity. As a consequence, there is fast developing a species of quack that not only does not use "patent medicines," but condemns their use by regular physicians. Men of this type base their appeals on "naturopathy," become "food experts," prescribe fasting, or two meals a day or five meals a day, give lessons in "deep breathing," conduct outdoor sanatoria, and employ light and air baths, dry cupping, mechanical vibration, intestinal lavage, water cures, electricity, osteopathic manipulations, "divine healing," etc. All these methods have value under certain conditions; the only objection is that when applied by the uneducated they are utilized to poor advantage. The fault lies not in the therapeutic means but in those who use them. Physicians sometimes confuse the two, and make the mistake of opposing the means and user alike. They reject good means of cure because employed by "irregulars."

[b] See G. Stanley Hall, "Adolescence," New York (Appleton), 1905, vol. 1, p. 235.

[c] See A. T. Schofield, "Power of Mind," London (Churchill), 1902, 2d ed., p. 277.

[d] See Osler, "Maryland Medical Journal," October, 1905, p. 420.

[e] See Professor Osler's address to St. Mary's Hospital, London, 1907.

The result is that the patient sometimes finds the best means of recuperation in the hands not of medical men, but of uneducated "physical trainers." The public will go and should go to those who will render the most effective help. In order that the medical profession may suppress quackery the way must be not to oppose the use of beneficial therapeutic agents in incompetent hands, but to get their use into competent hands by adopting them themselves. There is a quackery that is villainous and injurious. This should be suppressed. But there is another quackery which is well intentioned and which, in spite of ignorance, manages to do some good. The good in it should be appropriated by the profession. By always promptly absorbing the best the profession will be in a position to cast out the worst in "irregular" systems of therapeutics. It may then recover the ground which it has too often lost. There was no reason why it should have lost hundreds of thousands of patients to "Christian Science," except that these patients were for the most part benefited, and greatly benefited, by Christian Science after having received no benefit, and often injury, from the profession. "Easily physicians, without knowing it, can produce sickness by pessimistic prophecies, by anxious looks or words. Thus are diseases suggested (unconsciously) by the physician."[a] Had the profession made use of mental therapeutics not only could they have saved themselves the enmity of these hundreds of thousands, but they could have nipped in the bud the crude metaphysics which teaches the nonexistence of disease and death and the uselessness of any therapeutic agent except those employed by the promulgator. The example of so-called "Christian Science" is only one of several protests, more or less misguided, against the present practice of medicine.

Had all or most members of the profession conceded long ago the harmfulness of many, if not most, violent drugs it might have forestalled the present antidrug movement among the laity. The misguided antivaccination movement is simply the carrying to extremes of the antidrug movement.

The Greeks were probably the most hygienic people that ever lived and they knew nothing of modern scientific medicine, not even of the circulation of the blood. This shows that man's primitive knowledge or instincts may be sufficient to enable him to keep and develop health.

---

[a] Schofield, loc. cit., pp. 215-216.

The old code of medical ethics, though well-intentioned, was so inelastic and was so susceptible of misconstruction as often to block the way to progress. The magnitude and far-reaching effects of this evil were long ago recognized by leading minds in the profession, and after years of agitation such a revision was unanimously agreed upon in 1903 as makes the modern principles of medical ethics purely advisory and far more liberal than formerly. All restrictions as to consultations were removed, medical societies were thrown open to reputable physicians of every school of practice requiring scientific training, and agencies put in operation for such organization and cooperation and to encourage such liberty of individual opinion as is demanded by the spirit of the age. Under the most active efforts of the medical schools, societies, and journals it will doubtless require years of time for this liberal spirit to reach all members of the profession to the extent which is so desirable. But when this is done and when the public can be made to understand that it has been done the prejudice which has hampered the profession's usefulness, which has made it so difficult to secure and enforce health and medical legislation necessary for the protection of the highest interests of the people and which has so fostered and given opportunity for quackery, will gradually become ancient history.

A frequent lay comment on some members of the medical profession is that to be true teachers of health they must practice what they preach. A physician can not succeed in controlling drug habits or alcoholism if he has these habits himself. He can not fight "patent medicines" if he uses them himself.[a] He can not effectively fight the social evil if he himself practices abortion. The standards of the profession are high. It is the individual who is at fault. A clergyman who preaches purity from the pulpit while living a double life is disgraced. In the same way, now that physicians are assuming the function of giving instruction in orthobiosis and hygiene, they are being called to account for their own daily lives. Self-interest and altruism alike will lead to needed corrections. The physician in these days of preventive medicine should keep himself well. The challenge "Physician heal thyself" is being followed by the challenge "Keep thyself well." Example more than precept is a principle to be applied here as elsewhere. He can not induce his patients to diet or take exercise if he himself is addicted to the fleshpots and the easy chair. Many a physician to-day loses patients because he and his family are on the sick list, or because as a man he practices habits which as a physician he does not approve.

The physicians in this country now number about 130,000. Their calling is in some respects the noblest in the world to-day. During the present generation the profession has begun to be appreciated for its great services to public and private health and for its self-sacrifice, which is unequaled in any other profession except the ministry. It has now before it an opportunity such as never before existed. Those of us who believe in its mission look forward to incalculable blessings to suffering humanity from greater knowledge better applied.

---

[a] See A. Jacobi, Journal American Medical Association, September 29, 1906, p. 978.

SECTION 3.—*Institutional hygiene.*

The large cities have established special contagious hospitals, where prompt isolation of infectious cases may be enforced. The decrease of tuberculosis may be traced largely to hospital isolation.[a] Leprosy was the first disease to be quarantined[b] and its virtual disappearance in civilized countries has been due, at least in the opinion of many authorities, to the strict isolation methods universally adopted.

Of a different kind is the segregation of defective classes of the community. This has led to considerable conservation of their powers and abilities. Institutions for the deaf and blind in the United States contained 14,700 inmates in 1904, and spent for purposes of maintenance over $3,500,000.[c] In these schools the deaf and dumb and the blind are taught trades and professions, their usefulness being thus much enlarged.

The New York state commission on the blind recommended in 1907 a state board for the blind to conduct an employment bureau for the blind of that State, to establish schools, and to put into operation measures for the prevention of blindness. It is pointed out that of the 100,000 cases of blindness in the United States a great percentage is traceable to disease and accident of a preventable character. The commission estimates that of 1,000 cases in New York, 450 were possibly avoidable and 325 (or one-third) certainly so.

For the checking of insanity the crying need is a study of the causes of the malady with a view to its prevention. For, as Doctor Ditman remarks, nine-tenths of the inmates of our insane asylums are incurable, according to our present knowledge. He adds: "What an argument for the prevention of the disease!"[d] Much may be expected from the Phipps fund, for the study of insanity, recently established at Johns Hopkins University.

In the first place, our medical students should receive constant clinical instruction in mental diseases, particularly in their incipient stages. Almost equally important are popular lectures on the preventable and other causes of insanity given under the auspices of medical schools or local boards of health. Such lectures have been given in New York and Boston, and, judging by the attendance, must prove a valuable agency in diffusing a correct knowledge of the cause and development of mental disease. In this education of the laity popular treatises on mental hygiene would prove most helpful. Such a book as Doctor Clouston's "Hygiene of Mind" could, with advantage, be placed in the hands of every young person, and might even be adopted as a text-book in high schools. Certainly the physiology of mind is as deserving of popular consideration as that of digestion, respiration, and the circulation.

By a clearer insight into the beginnings of mental disease, gained through the popular lecture and a nontechnical literature, society will become so far enlightened that intelligent personal prophylaxis may be anticipated.[a] A knowledge of danger is the surest means of guarding against it. "The most obvious line of attack must be in the direction of the four great etiological factors of insanity, heredity, alcohol, syphilis, and environment. Abstractly considered these four causes are preventable or removable."[b]

---

[a] See Newsholme, "Phthisic death rate," Journal of Hygiene, July, 1906.

[b] See J. M. Eager, M. D., "The early history of quarantine," Yellow Fever Institute Bulletin No. 12, pp. 4–5.

[c] Census report on "Benevolent institutions," 1904.

[d] Ditman, loc. cit., p. 46.

As an intermediate step between home and hospital, the sanatorium offers both cure and prevention. Many tuberculosis sanatoria will take patients only in the incipient and early stages of the disease. Sanatoria are used by many as places of recuperation. The tired business man and the nervous housewife find at the sanatorium the quiet they need, and a week or two of rest enables them to escape threatened serious ills.

Many public institutions, in response to popular demand, are today installing methods and equipment that are essentially preventive. More than one department store in the large cities filters its air in order that patrons and clerks shall not feel oppressed by vitiation of the atmosphere. An indirect result is the prevention of tubercular and other diseases. A leading hotel in Philadelphia has pitched tents on its roof, where a large colony of well people—not sick—sleep out of doors, and the same hotel utilizes its roof in winter for a skating rink. Mothers' clubs are an increasing factor in the spread of a knowledge of hygiene. Recently a case came to light of a new member of a mothers' club who was feeding her 5-months-old baby on sausage, tea cake, etc., and giving it drugs when she wanted to go out. She was greatly surprised when informed of the wrong she was doing.

Growing interest in the science of home economics, already referred to, is an indication of our increasing realization of the importance of healthful homes in the community. While the number of schools and colleges which offer courses in higher domestic science, and in what might be called "true home economics," is growing, they are nevertheless still comparatively few. More teachers should be equipped with scientific knowledge regarding modern sanitation in order that they may give practical courses in grammar and high schools, and higher instruction should include the topics of hygiene and sanitation. Home making may be studied in many details, such as the construction of healthful houses, the purification of food and water supplies, and the cleansing of cities, whereby the enlistment of both boys and girls in all lines of home and municipal hygiene can be secured.

The churches are now joining in the health movement. The lead has been taken by the Rev. Elwood Worcester and Rev. Samuel McComb at the Emanuel Church in Boston. Trained physicians are employed for diagnosis and for general advice, but great emphasis is laid on the power of suggestion and of Christian self-control over bodily ills. The object is to get both patient and physician to stop "thinking sick and talking sick," as Doctor Goler has put it.

---

[a] A book which brings the subject home with unusual force to the ordinary reader is an autobiographical sketch by a recovered patient, "A Mind that Found Itself," by Clifford W. Beers, New York (Longmans, Green), 1908.

[b] Charles P. Bancroft, M. D., "Hopeful and discouraging aspects of the psychiatric outlook," address at meeting of American Medico-Psychological Association, Cincinnati, 1908.

SECTION 4.—*School hygiene.*

In every progressive country to-day the hygiene of school life is coming to be regarded of paramount importance. At the International Congress on School Hygiene, in London, August 5–10, 1907,[a] there were in attendance at least 500 delegates, representing the governments of the world and societies devoted to the advancement of human welfare, and in addition there were 1,500 individuals interested in the improvement of the health of school children and all that this implies. The fact was brought out at the congress that European countries, notably Switzerland, Germany, France, England, and Scotland, are doing more than the United States in the medical inspection of schools and that they are seemingly making plans for the improvement in every direction of the hygienic conditions of school life.[b] Even in Italy the leading statesmen are apparently convinced that the matter of chief importance at the present moment in their educational work is to place it, from start to finish, upon a hygienic basis.[c]

It is the unanimous opinion of all students of the matter that the neglect of the hygiene of school life in the larger sense is, first of all, more or less disastrous to a considerable proportion of the pupils.[d] With us, as well as in most European countries, children are compelled by the state to attend school for a number of years. Many of them suffer constantly from defective vision, hearing, and respiration, from nervous overstrain, and from other ailments which are greatly aggravated by the confinement and stress of school life.[e] Pupils are always exposed to infectious diseases. It is no unusual thing in our country to see a contagious disease sweep through a whole school so rapidly that the local board of health can hear of it and order the school closed only after the harm has been done.

Great as is the injury done by the spread of infectious diseases to children thus massed together in schools, the injury resulting from imperfect seating, lighting, ventilation, and sanitation of school buildings is still more serious. In every part of our country, as well as in the progressive countries of Europe, those familiar with the situation are appealing most urgently for improvement in the physicial basis of education. This is not the place to recite the disabilities which are said by men competent to speak on the subject to result from keeping children for at least eight years in confinement and at hard mental labor under conditions that waste their vitality and develop bodily defects and habits prejudicial to health. The list of such disabilities is a long and impressive one.[a] Unfortunately, we do not, as a people, sufficiently appreciate that the character of social life with us is changing rapidly, and that consequently our children are particularly susceptible to certain diseases and defects; to wit, those arising from the adoption of an indoor life of comparative muscular inactivity, with greatly increased demands made upon particular organs, such as the eyes and the brain.

---

[a] The proceedings of the congress contain papers by distinguished physicians and educators upon every phase of the hygiene of school life. Existing evils are pointed out and remedies suggested. Summaries of the papers may be found in the Nineteenth Century, September, 1907, pp. 388–394.

[b] In addition to papers presented at the International Congress on School Hygiene, see the following: A series of articles in the School Review (University of Chicago) for 1907, by Prof. Hermann Schwartz, entitled "The study of experimental pedagogy in Germany." Many articles in the magazine Zeitschrift fur Schulgesundheitspflege show the great interest in Germany in school hygiene. Professor Binét, of Paris, has established a laboratory for the study of childhood in relation to educational work, and he will give particular attention to problems concerning physical defects and mental and moral shortcomings. For other such institutions see The Psychological Bulletin, Vol. VI, March 15, 1909, pp. 84–103.

[c] See, for example, Professor Garlanda's "Il Terzia Italia," in which he shows the only way in which Italy can regain her old-time vigor and efficiency.

[d] See M. V. O'Shea: "Dynamic Factors in Education" New York (Macmillan), 1906, Part II, where the whole subject is discussed.

[e] See Oppenheim: "The development of the child," Chap. V. Also Tyler: "Growth and education;" Burbank: "The training of the human plant;" Burk: "From fundamental to accessory," etc.; Pedagogical Seminary, Vol. VI, Kræplin: "A measure of mental capacity," Popular Science Monthly, vol. 49.

Doctor Cronin, of New York, maintains that in a school population of 650,000, 30 per cent of the children were from one to two years behind their proper class. Ninety-five per cent of these backward children were so principally because of defects of eye, ear, nose, or throat, which could easily be detected and remedied through effective medical inspection. Experiments at home and abroad have proven beyond any doubt that the majority of children of this sort, when given proper medical treatment, improve markedly in intellect and general conduct. The State attempts to educate these children, but its effects are to a large extent wasted. Doctor Osler calculated that in the special city to which reference has been made there was, on account of a lack of medical supervision of educational work, a yearly financial loss of $1,666,666; and of course the loss which came from moral deviation due to defective physical functioning was of far greater importance. Doctor Osler said recently, in effect, that he considered it of greater importance to the nation that the question of sound teeth be intelligently considered than that the consumption of alcohol be restricted, important as the latter problem is. In similar vein, Doctor Newton reports a case of an old, unhygienic school building in a small town being fitted up with a ventilating system, with the result that the cost of the improvement was saved in a short time in salaries that otherwise would have been paid to extra teachers for taking the place of those made sick by the foul air in the building.

We now know the major effects at least on intellect and temperament of sense defects, adenoids, decaying teeth, and minor physical deformities; and we also know how such deviation from normality can be readily and inexpensively detected and remedied,[b] but there are whole States where no advantage whatsoever is taken of this knowledge, and in practically every State in the country there are communities in which absolutely no attention is paid to any of these matters. The people go on in traditional ways, trusting to luck and disregarding the changes taking place in society.

[a] See Shaw: "School hygiene;" Keating: "Mother and child;" Ballantyne, in the Lancet, Vol. 2, 1890; Bancroft: "Physical Education Review," Vol. VII; Rowe, "The lighting of schoolrooms;" Burrage and Bailey: "The Sanitation and decoration of school buildings." The Magazine of School Hygiene, published under the direction of the School Hygiene Association, contains in each issue articles showing the evils resulting from unhygienic conditions in the schools.

[b] See, for example, two books by Doctor Warner, of London: "The Study of Children" and "The Nervous System of the Child." The city of Chicago maintains a department for the study of backward and defective children in the public schools.

The health of our school children, then, should be conserved by a system of competent medical inspection[a] which should secure the correction of defects of eyes, ears, teeth, as well as defects due to infection or malnutrition. In Europe—

> all the investigations disclosed an astonishing amount of ill health among school children; and though the variations from the normal were found to differ in degree, they were on every hand alike in kind. In nearly every instance they were more pronounced in girls than in boys, and were often most manifest in scholars of the better social classes. Thus there were discovered the following percentages of morbidity among school boys: In Great Britain, 20; in Denmark, 29; in Germany, 30; in Copenhagen, 31; and in Sweden, 37. The percentages noted among the girls were: In Great Britain, 16; in Copenhagen, 39; in Denmark, 41; in Lausanne, 43; in Germany, 50; and in Stockholm, 62—an average morbidity for boys of 29 and for girls of 42 per cent.[b]

Similar results have been reached in certain cities of the United States. A "committee on the physical welfare of school children" in New York City examined New York school children and found that[c]—

66 per cent needed medical or surgical attention or better nourishment.

40 per cent needed dental care.[d]

38 per cent had enlarged glands of the neck.

31 per cent had defective vision.

18 per cent had enlarged tonsils.

10 per cent had postnasal growths.

6 per cent were undernourished.

Dr. Walter Cornell has been making an extensive study of eye strain among school children. These were his findings:[e]

> The relationship of poor vision to scholarship was studied in 219 children. As will be noticed, the difference in marks between those with normal and those with bad vision is greatest in arithmetic and spelling, which studies require more extensive use of the blackboard.
>
> *Scholarship percentages obtained.*
>
> | Children with— | Arithmetic. | Geography. | Spelling. | Average. |
> |---|---|---|---|---|
> | Normal vision | 79 | 69 | 76 | 75– |
> | Fair vision | 70 | 71 | 77 | 73+ |
> | Bad vision | 66 | 70 | 71 | 69 |
>
> In New York City 29.5 per cent of 79,069 children examined suffered from defective vision. In London 26 per cent of 20,000 children examined by eight

[c] Ditman, loc. cit., p. 41.

[d] This seems a low estimate in spite of the fact that it does not include all cases of decayed teeth, but only those that have been neglected. See Dr. William R. Woodbury, "The People's Disease: How to Prevent it," Boston Medical and Surgical Journal, March 26, 1908.

[e] "Backward Children in the Public Schools," Philadelphia (Davis), 1908, p. 7.

opthalmologists had defective vision, and of this number 12.5 per cent suffered from vision of one-half or less. The author examined personally 1,156 children and found 34 per cent with defective vision, and of this number 6 per cent with vision one-half or less. A small proportion of this number only is fitted with glasses. The rest suffer from real eye strain. The fault of this deplorable condition is divided among physicians, school-teachers, and parents. Ignorance of the existing facts, indifference, and poverty are the real factors to be dealt with.

Eye strain is the chief source of the functional diseases of our citizens. It begins in early childhood and continues until senility is complete. It is bound to occur in every individual some time in his life, to a greater or less degree. It is almost the sole cause of headache, migraine, sick headache, the most frequent and habitually morbidizing of human diseases. It is the frequent cause of gastric and digestional diseases and of nervous and mental diseases. With ocular function it conditions the origin of spinal curvature, either directly or indirectly, through the pathogenic writing posture. Lateral spinal curvature, the effect of visual function, becomes a new secondary source of multifarious morbidities, such as neurasthenia, pelvic diseases, hysteria, etc. It has been demonstrated that 27 per cent of European school children have lateral spinal curvature at the age of 14, and I have proved that at least 70 per cent of our own 16 to 18 year old young men of the educated classes have this disease. Surprise at the fact will soon become horror at the national and social tragedy which these true figures indicate.[a]

Investigations in other cities and States[b] have shown similar results, in view of which it is a conservative statement to say that from one-half to two-thirds of our school children need medical treatment of some sort.

At least one year in each division of schooling, elementary, secondary, and collegiate, is lost to the majority of students because of unnecessary sickness or dullness caused by improper living.[c]

That physical defects are responsible for much of the backwardness of children, and for a large share of truancy and incorrigibility, is the opinion of many educators.[d] In order to correct physical abnormalities and thereby to hasten mental and moral progress in school life, a number of cities have instituted medical inspection of schools.

So far as inquiry has been able to discover, there were in the month of June, 1908, 70 cities in the United States, outside of Massachusetts, having some form of medical inspection of schools. In the State of Massachusetts 32 cities and 321 towns had systems more or less complete. It is at present impossible to compute, or even to closely conjecture, how many children these systems reach at the present time. It is entirely certain that they do not reach all of the children in the schools of those cities and towns where systems of medical inspection are actually or nominally in operation.[e]

New York City employs 150 physicians, who visit each public school once a day, shortly after 9 o'clock, to examine those children set aside by the teacher as requiring attention. Chicago employs nearly 100 physicians to visit her public schools. In Chicago during the ten months of the school year ended June 26, 1908, the medical inspectors of schools examined 406,919 pupils.[a]

[e] Letter from Dr. Luther H. Gulick.

And one health officer, Doctor Chapin, of Providence, has even established a special fresh-air school for children who suffer from certain forms of tuberculosis or who come from tuberculous families. He says concerning it:

> Our fresh-air school has only been running since last January (1908), and, of course, we have no very definite results. All of the children without exception improved in health, and gained in strength, and also showed good mental progress. The cost of the school per capita is only about 50 per cent more than in the ordinary schools, and we believe that the expense is fully justified. If we had a large enough school, so that it could be graded, the cost of education would, owing to saving in fuel, probably be less than in an ordinary school.

Several States are making progress in these directions.

> Connecticut, Massachusetts, and Vermont have passed laws making examination of eyes, ears, and method of breathing of the public scholars compulsory, while New York, Illinois, and some other States of the Middle West depend upon the voluntary cooperation of the teachers in making this examination. It would seem, however, that whether it remains voluntary or becomes compulsory, its success will be greatly enhanced if women who are conducting teachers' institutions in the department of education devote a half hour or an hour to the exposition of the necessity of such an examination and also in explaining the method in detail and the method of tabulating the results, so that the teachers may be familiar with the tests, etc., when they have to make them. With the great power lodged in the department of education in this State, it would seem justifiable to make this compulsory.[b]

We in this country should profit by the experience of older countries in respect to school hygiene. Switzerland has led the nations in its concern for the physical welfare of its children. A number of other European countries are beginning to imitate Switzerland in attaching supreme importance to health and hygiene in educational work. There is now before the English Parliament a bill the purpose of which is to establish a national system of medical inspection of schools, and it seems probable that this measure will be enacted into law.

It is generally recognized by physicians and educators to-day that many children in the schools are being seriously injured through nervous overstrain.[c] Throughout the world there is a developing conviction that one of the most important duties of society is to determine how education may be carried on without depriving children of their health. It is probable that we are not requiring too much work of our pupils, but they are not accomplishing their tasks economically in respect to the expenditure of nervous energy. Some experiments made at home and abroad seem to indicate that children could accomplish as much intellectually, with far less dissipation of nervous energy, if they were in the schoolroom about one-half the time which they now spend there. German educators and physicians are convinced that a fundamental reform in this respect is needed. In fact, among school children we are learning the same lesson as among factory employees, viz, that high pressure and long hours are not economy but waste of time.

[c] See Dr. Adolph Meyer, "What do Histories of Cases of Insanity Teach Us Concerning Preventive Mental Hygiene during the Years of School Life?" The Physchologic Clinic, June 15, 1908.

In American cities one of the greatest needs to-day, in order to conserve the vitality of children, is the establishment of playgrounds easily accessible to all the children of any community. We are told that the physical and the mental are inseparably joined together, and if the one is defective the other will suffer through sympathy. Now it appears to be impossible to develop the child physically in any way so effectively as through active play. Formal gymnastics can accomplish relatively little. The child must have some end to attain that arouses its enthusiasm, and that demands agility and strength and endurance; then its whole bodily mechanism will work together in harmony to achieve this end. And this is what a physical training seeks to accomplish—to make the body a fit instrument for the mind. Let the child have some place where it may not only play games freely without fear of the police but where it may run and jump and climb and swing and work in sand and throw stones and wrestle, and it will not fail to make the most out of the body nature has given it as a housing for a sound and efficient mind.

Even if playgrounds were of no value in social development, they would still be of inestimable service in keeping children out of crime and lessening expense for police, courts, reformatories, hospitals, and prisons—a point which was strongly emphasized in the report of 1897 of the committee on small parks in New York. If a boy's energies are not used up in wholesome activity they will surely find expression in illegitimate conduct. The boy will prey upon the institutions which prevent him from living a natural life. "The greatest enemy to the police is the boy," said a high Philadelphia official recently. Go to the storekeeper, to the shopkeeper, to the housekeeper, and you will hear the same story. The boys steal, break windows, insult, afflict, upset one thing and another, and would do almost anything they hear or see in order to satisfy that burning instinct for play. "These beginnings of vice and crime were the only outlets they have had for the powers with which nature has endowed them. These practices were their only or chief amusement, and thus happiness to them became synonymous with vice and fiendish delight in evil doing."[a]

But in studying the life on the playgrounds the same official sees that they lay the foundations for—

> strong, manly, bright, and happy lives, rescued from the evil habits and tendencies that produce misery and wretchedness. * * * Through their play in this manner the young are taught how to live together, how to respect each other's rights, how to be kind, gentle, pure, in language as well as in conduct. The boy's mouth is not defiled by tobacco, liquor, or profane language. The disrespectful and vulgar treatment which young boys and girls inflict upon each other in the street is done away with. The playground influences are brought into the home, where the younger brothers and sisters treat each other much differently from the way they do now; or, to put it the other way, the influences of the home, the school, and of the church are thus extended outside over the whole life of the child.[a]

To playgrounds may be joined school gardens, which Superintendent Maxwell in New York has shown would not be expensive, or open-air gymnasia, or any other equipment that will give children the opportunity to develop physically.

---

[a] Secretary of Philadelphia Culture Extension League.

Physical education is a part of the training in many public schools and in a still greater number of private schools, but there is room for improvement. After pointing out, in a recent article on physical deterioration, that Germany, France, and Austria have improved their physical development by compulsory physical training in all civil and military educational institutions, the Rev. Percy Stickney Grant advocates the instalment in the United States of:

> 1. An effective system of physical education as a recognized part of all public-school systems. By "effective" I mean one that does for a boy, as far as his physique is susceptible, what army setting-up exercises do for a recruit.
> 2. Athletic exercises in schools, using gymnasia, baths, etc.
> 3. Open-air exercises and sports under efficient supervision.
> 4. Summer camps free of cost, and compulsory attendance for boys of school age.[a]

The study of hygiene and physiology has been part of the public school curriculum for some time, but has been regarded by physiologists as a somewhat partisan and unscientific treatment of the physiological effects of alcohol and tobacco. It should be recognized, however, that it has had a salutary effect and has given school children a better idea of what alcohol means than the most of them had before.[b] Local topics of sanitation may well be taken up, as in New Haven last year when the interest of all the city school children was enlisted in behalf of a "clean city." Doctor Stiles, of the Public Health and Marine-Hospital Service, has proposed an annual "health week" in the public schools, and this proposal has found favor in several States. In Georgia Chancellor Barrow has proposed an annual "health day" in the public schools of that State, which would be devoted to lectures on sanitation, on the dangers to be expected from unscreened windows, and on the character of the hook-worm disease, with suggestions as to its elimination.

> At present the schools look to parents to instruct their children in the supposedly simple matters of regulating eating and drinking, exercise, habits of work, and sexual habits, while the parents vaguely hope (if they think about such matters) to be relieved of these embarrassing duties through the schools. The truth is that neither parents nor schools are to-day able to give this much-needed sort of education. The remedy must be provided by the schools, which in their eagerness to impart conventionalized facts are now quite blind to some of the most pressing needs of their pupils. Through the schools and universities (or other appropriate organizations) the parents of the future must be educated both as to the facts and the moral aspects of bodily hygiene. And it seems not unreasonable to hope that some of the lessons now learned only by bitter experience, after much that is best in life has been sacrificed to ignorance and uncurbed impulse, will be assimilated sufficiently early in life to mitigate materially the lot of a not inconsiderable part of mankind. I beleve the lengthening of the span of human life to be among the attainable results of such teaching. Is it not likely that as men grow wiser an increasing number will deliberately strive so as to regulate their lives as to improve the expectation of crowning well-spent days with the peculiarly fine satisfaction of old age?[c]

If the school building were a model of ventilation, lighting, and sanitation, it would not only conserve the health of the school children, but also serve as an object lesson for hygienic instruction. In the same way cooking and domestic science classes could be made to serve the double purpose of providing a hygienic noon meal and training the school children, especially the older girls, in the principles and practice of this vitally important subject. Our schools are suffering from the conventional idea that education comes from books. Education is preparation for life, and should make use of every efficient method and element, manual training, athletics, observational nature study, laboratory experiments, and object lessons of all sorts, as well as book instruction.

SECTION 5.—*Voluntary and business organizations.*

A host of distinctly voluntary associations are working for the improvement of hygienic conditions. Among them may be mentioned the National Association for the Study and Prevention of Tuberculosis, the Society for Sanitary and Moral Prophylaxis, the Chicago Society of Social Hygiene, the Connecticut Society of Mental Hygiene, the national and state child labor committees, the Congress on School Hygiene, the Children's Aid societies, the Sunshine societies, the American Playground Association, the Visiting Nurses' Association, the Red Cross Society, the American Association for Labor Legislation, the numerous temperance organizations, university settlements, institutional churches, Young Men's Christian Association and kindred associations, the American Physical Education Society, the Boston Health Education League, and the American Health League established by the Committee of One Hundred on National Health.

That various large bodies of men are waking to the importance of health study is shown by the appointment, at the last annual meeting of the Associated Fraternities of America, of a committee on infectious, contagious, and hereditary diseases, with Doctor Craig, of Chicago, as chairman. Labor unions may well follow this example and provide for the education of their members in the subject of hygiene. This could be effectively combined with their endeavors to shorten the hours of labor. Especially unhygienic is the arrangement by which a man has no interest in his work beyond that represented by his pay envelope. This fact has been recognized by some farsighted employers of labor, with the result that they now employ social secretaries or "welfare workers" to look after the general well-being of employees. A social secretary watches over the health, comfort, and happiness of the force during working hours, establishes lunch rooms, rest rooms, mutual aid associations, thrift funds, and penny provident banks. Employers, as a rule, become eager for practical suggestions and expert advice on the well-being of their employees as soon as the matter is called to their attention. Doctor Favill, president of the Chicago Tuberculosis Institute, after speaking before the Commercial Club, was urged by 15 or 20 of the large employers present to undertake investigation of their establishments and to make recommendations.

Dr. Hubert Higgins describes an interesting experiment carried out in a mill near Paris, where there were employed 44 men and 75 women and children. A medical officer was employed to supervise the sanitary appliances and regulations and to give careful instruction and explanations. He held practical instruction classes with the mothers, lecturing on diet and cooking, cleanliness, the way to take body temperatures, and how to look at the children's throats.

> This experiment was entirely successful, though the doctor lived in Paris. There was not a single death in three years. There were one or two cases of scarlet fever and diphtheria, that were promptly and effectively isolated. This experiment was not philanthropic, but financial, the employer realizing that he had better value in work from healthy hands.[a]

A few factories now use or permit the use of a reader to read to their employees, where the manual nature of their work is such as not to be hindered by listening to a story. Others use a piano and have their employees march in and out to music. The curious physiological relations between rhythm and work are now being observed by physiologists. Laboratory tests with ergometers seem to show that more work can be done under the stimulus of rhythm. Soldiers and sailors have for ages made use of music and rhythm, and it would not be beyond the range of possibility if the factory system should in some cases find more use for it than at present.[b]

Unconsciously, business corporations have also made changes which tend to improve the sanitary conditions under which their employees work. In a large telephone exchange in Chicago the perfect working of the apparatus was much hampered by dust, so that insulation was seriously affected. To obviate this condition an expensive system was put into operation, by which the air was washed and pumped into the rooms under ideal conditions. What the company aimed at was the perfect health of its apparatus, but it gained in addition a decided improvement in the health of its employees.[c]

Another similar organization, the New England Telephone and Telegraph Company, at Cambridge, Mass., ventilated its offices during the winter of 1907–8 with unusual care, with the result that the number of days of work lost by its 60 female employees was cut in half.

The need of industrial efficiency is driving business men to demand temperance or even total abstinance among their employees. This is one of the most powerful motives to-day working against the abuse of alcohol. In the South employers and the public see that negroes who drink are inefficient and dangerous. Railway officers and the traveling public realize that public safety requires sober locomotive engineers and firemen. Even drinking among sailors is being discountenanced. Doctor Grenfell, the missionary among the Labrador fishermen, says: "Why don't I want to see liquor used at sea? Because when I go down for a watch below, I want to feel that the man at the wheel sees only one light when there is only one light to see."

Among semipublic institutions with power to exercise prodigious influence in improving the public health are the life insurance companies. Just as fire insurance companies make efforts to decrease the risk of fire, so life insurance companies might well join in public health movements to effect a reduction in the human death rate.

While the financial motive is sordid, it should be utilized because of its tremendous power. The insurance companies to-day represent an invested capital of over $3,000,000,000. An actuary recently remarked to me, in connection with this subject, that they could without feeling it contribute great sums annually to the preservation of public health. When insurance companies were established, the old dictum that human vitality followed a fixed law served probably to exclude the idea of preventing death claims rather than paying for them. Now that we are learning the preventability of disease, the time must come when insurance companies will take an active part in the fight. Even a single company would probably make a good investment if it sought to educate its own "risks." But a far more effective method would be a combination of all companies to improve public health through the enactment of public legislation—by Congress, state legislatures, municipal governments, and in numberless other ways.[a]

---

[a] Hubert Higgins, "Humaniculture," New York (Stokes), 1906, pp. 209-211.

[b] See Karl Bücher, "Arbeit and Rythmus," Leipzig, 1902.

[c] See Outlook, May 26, 1906.

Among some official agencies meant to promote the social welfare are two recent commissions appointed by the President—the Homes Commission, of 1907, appointed for the purpose of studying the housing conditions in the District of Columbia, and the Commission on Country Life, appointed to study the daily life of the farmer. Farm sanitation will be especially considered.

Finally, there is a public yet voluntary agent in the progress of hygiene that must not be overlooked, namely, the modern periodical. Not only do the daily papers devote much attention to questions of health and hygienic reform, but the popular magazines have taken up the fight against disease, and are educating the popular mind, more surely than is realized, concerning the natural and normal way of life. It is necessary to add, however, that these same periodicals often nullify the benefits derivable from their reading matter by printing the most harmful of patent medicine, quack, drug, and alcoholic advertisements. Public odium should attach to newspapers and magazines that advertise hurtful nostrums. It is impossible to estimate the harm wrought to the public health each year through such advertising.[b]

The daily papers are especially culpable in this regard, but weeklies and monthlies are not wholly clear of the taint. When a newspaper's advertising space is once bought by quacks or nostrum sellers, its news columns become closed at once to matter considered objectionable by such advertisers. Frequently news items reflecting directly or indirectly on quackery are suppressed. Notable examples of publications that have taken strong ground against such advertising are Collier's Weekly, The Outlook, The Ladies' Home Journal, and a few—a very few—daily papers.

---

[a] Since the above was written the Committee of One Hundred on National Health has urged this matter before the Association of Life Insurance Presidents, which body has appointed a committee to draw up plans. Also the Metropolitan Life Insurance Company has organized a bureau of cooperation and information to aid in distributing information to policy holders of the "industrial" class.

[b] For further discussion of this topic see a pamphlet by Samuel H. Adams on "The Great American Fraud," reprinted by the American Medical Association from a series originally appearing in Collier's Weekly, and "A Century's Criminal Alliance between Quacks and Some Newspapers," by Champe S. Andrews, Publications of the Committee of One Hundred, 1907.

CHAPTER IX.—*Conservation through personal hygiene.*

SECTION 1.—*Its importance.*

Following public and semipublic hygiene, we arrive at what is in many respects the most important subject of all, personal hygiene. It is quite true that the individual is often at the mercy of unclean streets, bad drainage, impure water and food, and other shortcomings of public and semipublic hygiene. On the other hand, his own personal interest is necessary in order to form the public opinion which alone can result in effective public and semipublic hygiene, while that interest is still more necessary to make such hygiene apply directly to his own person. Clean streets are of use only as they make the air breathed purer, but they are of little avail to the household which does not ventilate its rooms or which keeps them in a state of filth. The milk supply of a city may be ideal, but all the pains to make it so will be set at naught if the individual consumer allows the milk to be contaminated after it is delivered. The labeling of foods and drugs will not prevent self-poisoning through alcohol, nor will the elimination of preservatives from foodstuffs and the enforcement of sanitation in their manufacture be of avail if in their preparation for the table they are subjected to disease and dirt. Thus at every point of hygienic progress, there must be individual cooperation with public efforts.

When, contrariwise, health organizations and officials are inefficient, the individual may, in spite of these difficulties, often maintain good health. In New York a woman who was the occupant of a tenement overcame tuberculosis by sitting daily on her fire escape. The air was not the best, but it was much better than indoors. Similar results have been obtained by workmen in Brockton shoe factories, who, in spite of insanitary working places, and without cessation of work, conquered tuberculosis by sleeping on the roofs of their houses at night.

Observation shows that many, possibly most, of the world's most vital men and women have virtually made over their constitutions from weakness to strength. Cornaro, the famous nonogenarian, Kant, and Humboldt are cases typical in different fields of achievement. Cornaro, a Venetian nobleman born about the middle of the fifteenth century and given up to die at the age of 37, foreswore all unhygienic habits and began to live "the temperate life," his abstemiousness applying especially to food. His age at death is variously estimated, but he lived to be at least 97. When over 90 he wrote a treatise on longevity, laying down as the chief rules of a normal life, care in eating and drinking, and the avoidance of melancholy and passion.[a]

Centenarians have usually been persistent followers of some rule or rules of rational hygiene, even though unconsciously.[b]

Metchnikoff points out[c] that part of the supposed inheritance of longevity may not be inheritance, but similarity of environment, and that it very frequently happens that husband and wife both live to be over 100. This could scarcely happen by accident, but must be due to similar habits or environment.

---

[a] See L. Cornaro, "The Art of Living Long" (English translation, Wm. F. Butler, Milwaukee), 1903.

[b] Metchnikoff, "The Prolongation of Life," p. 141.

[c] Ibid., p. 86.

Humboldt confessed to a fellow-student that in the first years of his childhood his tutors were doubtful whether even ordinary powers of intelligence would ever be developed in him, and that it was only in the advanced part of his boyhood that he began to show any evidence of mental vigor. As a boy he suffered from debility which not infrequently produced great prostration.[a]

Of recent examples may be mentioned a young physician who was given up to die of tuberculosis five years ago, but who to-day can run 25 miles without a rest; and Horace Fletcher, who in his 46th year was rejected for life insurance, but who later not only obtained his insurance, but proved his powers of endurance by cycling 190 miles on his 50th birthday.

And not only can weakness, if recognized early enough, be turned into strength, but strength, however great, may be dissipated in an incredibly short time.

Personal hygiene means the strengthening of our defenses against disease. Public hygiene seeks to destroy the germs before they reach our bodily defenses. These two branches of hygiene are simply the two forms of warfare, defensive and offensive. Both are of transcendent importance, but the defensive warfare is more within our power. We always have our defending garrison, the white blood corpuscles, to deliver us from our enemies.[b]

SECTION 2—*Branches of personal hygiene.*

Personal hygiene comprises hygiene of environment (air, soil, dwelling, clothing); hygiene of nutrition; and hygiene of activity.

Man is more dependent upon the atmosphere than upon any other environmental factor. His body is bathed in air and his most vital function, respiration, depends upon it. Deprived of air, he will shortly suffocate. If the air is confined and impure, his health will be affected. Ideal air should first of all be pure—i. e., free from injurious bacteria, from dust, smoke, and noxious gases. It should also conform to certain standard conditions of humidity and temperature. In this field lie the sciences of climatology and meteorology. Man learned long ago how to make himself almost independent of climatic and atmospheric conditions by the use of dwellings and clothing. These contrivances, however, while protecting him from the elements, have brought evils of their own. The great scourge of tuberculosis, for instance, is principally an indoor disease.

Intimately related to the appropriation, through the lungs, of oxygen from the atmosphere is the ingestion of food and drink through the alimentary canal. Normal health conditions demand in the case of ingested materials, as in the case of respired air, the greatest possible purity, freedom from injurious bacteria, and the absence of substances hurtful mechanically or chemically.

Finally, the ideal conditions of health require perfect balance of work, play, and sleep.

---

[a] "Life of Alexander von Humboldt," by Lowenberg Ave-Lallewort and Dore, translated by Jane and Caroline Lassell, New York (Lee & Shepard), 1873, Vol. I, pp. 30–32.

[b] Metchnikoff, "The New Hygiene," p. 14.

While absolutely perfect conditions in these three branches of hygiene are unobtainable, hygienic progress consists in approaching these ideals as closely as possible.

The rules of personal hygiene are expressed in standard medical works on the subject. There is nothing novel in the brief résumé which follows. The radical changes in habits of living which are now being advocated and to some extent practiced imply nothing new. They have, for the most part, long been commonplaces of the medical profession. The knowledge is old. It is the application which is new. Medical men have long been telling their patients to get plenty of fresh air and to masticate their food. But until recently their advice has fallen on deaf ears.

SECTION 3—*The hygiene of environment.*

Air hygiene deals first of all with ventilation.[a] The importance of properly ventilating houses is so great that to secure this end the architecture of houses will have to be changed. The worst historical instances of bad ventilation are the imprisonment and virtual suffocation of 146 persons in the "Black Hole" of Calcutta and the confinement of 300 men in an underground room after the battle of Austerlitz. The evils of overcrowding come mainly from exhaled air and from the effluvia thrown off by the skin. Not only does overcrowding bring bad air, but it also increases the opportunity for infection.

The air in our houses has impurities of its own. Oil and gas vitiate it. Electric lights are hygienic in this respect. Air is never quite free from dust impurities. Aitkin estimates that country air carries 2,000 dust particles per cubic centimeter, city air 3,000,000, and inhabited rooms 30,000,000.

In a clean hospital ward, when air was agitated by dry sweeping, the number of colonies of bacteria collected on a given exposure rose from 26 to 532, showing the effect of ordinary broom sweeping. The broom is now being replaced by the carpet sweeper, and the carpet sweeper in turn by the vacuum cleaner. Each step represents progress in the elimination of dust. The removable rug is in this regard an improvement over the carpet.

Air may even be poisoned by the chemicals contained in wall paper or in the plaster of a brick and mortar dwelling.

The one place where the individual has more control over the air he breathes than anywhere else is his sleeping room. He may be powerless to control the air in his place of work, or even in the rooms where he lives during the day. But, except where he shares a bedroom with others who are averse to modern ideas of ventilation, he can largely control the air supply during sleep, and this means during one-third of his whole time. He can open wide his windows and in many cases arrange actually to sleep out of doors. The growing practice of sleeping out of doors is one of the most significant signs of the times. Only those who have tried it realize the benefits. The air supply in public places would be under the control of individuals, if organized in protest; and our churches, theaters, public halls, railway coaches, and railway sleepers would be properly ventilated if the public demanded improvement. Such a "score card" as Prof. John R. Commons has devised for measuring the relation of housing conditions to an ideal standard might well be used in measuring the health utility of public places.

---

[a] See Richards and Woodman, "Air, Water, and Food," New York (Wiley), 1904; also Carpenter, "Heating and Ventilating Buildings," New York (Wiley), 1905; Sykes, "Public Health and Housing" London (King), 1901, 216 pp.

The windows of living and work rooms may be opened in summer and somewhat in winter, provided a window board is used, to deflect the cold air upward from the sill. It then does not form a cold stratum on the floor, but mixes evenly with the air of the room. This simple device would go far to solve the question of winter shut-ins and their ailments. In many cities sleeping balconies are not uncommon among the dwelling houses.

The many benefits from a pure air supply are only beginning to be realized. For instance, as long as "the outdoor life" is lived a cold is almost impossible. Army officers have noted that as long as the men are on the march and sleep outdoors they hardly ever have colds, but that they become troubled with these as soon as they get indoors. Franklin, a century ago, knew these facts, though few of the present generation are acquainted with them. He believed "that people who live in the forest, in open barns, or with open windows, do not catch cold, and that the disease called 'a cold' is generally caused by impure air, lack of exercise, or from overeating." He came to the conclusion that influenzas and colds are contagious—a doctrine which, a century and a half later, was proved, through the advance of bacteriological science, to be sound. The following sentence exhibits remarkable insight, considering the state of medical art at that time: "I have long been satisfied from observation that besides the general colds now termed 'influenzas' (which may possibly spread by contagion, as well as by a particular quality of the air), people often catch cold from one another when shut up together in close rooms and coaches, and when sitting near and conversing so as to breathe in each other's transpiration; the disorder being in a certain state." In the light of present knowledge what a cautious and exact statement is that.[a]

John Muir, the geologist and naturalist, says that he finds home the most dangerous place he can visit.

> As long as I camp out in the mountains without tents or blankets I get along very well, but the minute I get into a house and have a warm bed and begin to live on fine food, I get into a draft, and the first thing I know I am coughing and sneezing and threatened with pneumonia, and am altogether miserable.

Atmospheric evils come from improper ventilation, and affect either the respiratory organs of the body or the skin. It has been supposed until recently that the presence of carbon dioxid gas in vitiated air was the chief evil caused by such air. Impure air will affect the lungs harmfully, but not till the amount of carbon dioxid contained is very large. Guinea pigs, on which the effects of bad air were observed, were not seriously affected by the carbon dioxid till it amounted to 14 per cent of the volume of the air. Flügge and others have found that the evil of close atmospheres is largely a result of elevated temperature, humidity, and absence of air currents. Tests were made on men who sat in impure air, but breathed pure air through tubes, and they presented all the symptoms usually resulting from bad ventilation.

---

[a] From "Benjamin Franklin as Printer and Philosopher," address of President Charles W. Eliot before American Philosophical Association, April 20, 1906.

Air baths have been shown to be as important for bodily health as water baths. For this purpose porous clothing should be worn and no more of it than is needful. Impervious cloth and rubber are probably injurious as clothing. Loosely woven worsteds, or linen and cotton mesh are best adapted to let the air play on the skin. Clothing, to be hygienic, should not constrict the body. Tight shoes, and especially tight corsets, are distinctly injurious, and the injury to mothers from the latter may be felt by the next generation. Another insanitary feature in clothes is the trailing skirt, which drags indoors the sputum of consumptives and germ-laden dirt from the sidewalk.

Closely connected with air and ventilation is light. The benefit of sunshine in killing germs and improving bodily vigor in every way is too well known to need more than mention. Tuberculosis and other germs thrive only in dark, damp, ill-ventilated places.

Light has its most important bearing on the human health through the sense of sight. Its relation to eye strain has been discussed elsewhere. Headaches, backaches, indigestion, hysteria, and epilepsy are often aided by glasses.

SECTION 4.—*The hygiene of nutrition.*

A primary necessity for hygienic living is good drinking water. The modern man of means insists upon good water, and, as a result, the traveling public is now able to get first-class water in cars, hotels, and other public places. The improvement was brought about by the appreciation by the consumer of the danger of drinking impure water. It is the consumer who has it in his power to bring about the necessary reforms in public hygiene. When he really values hygienic environment producers will supply it. Professor Sumner has told us that persons in the middle ages sometimes drank out of their castle moats, which contained sewage. Even in New York to-day the roof tanks are sometimes used as baths or laundries; and they accumulate dust and flies very rapidly. Only a few years ago the aldermen in a prominent western town laughed out of court a physician who called their attention to dangers which were real, but which they believed imaginary, from a polluted water supply.

The scientific study of diet has only just begun and few authoritative results can yet be stated. To avoid a lengthy review of controversial literature it seems best to pass the subject over rapidly, referring the reader for further information to some of the principal books on the subject.

We have already seen the surprising improvement in endurance which followed the adoption of thorough mastication in place of the ordinary food bolting. Mr. Gladstone used to be noted for his care in slowly masticating his food, and latterly Mr. Horace Fletcher has aroused the interest of the public in the subject in Europe and America.[a] He has also stimulated a large number of physiologists to study the subject of mastication, the protein ration, and their relation to strength and endurance.

---

[a] See Horace Fletcher, "The A, B–Z of our Own Nutrition," New York (Stokes), 1903; Dr. Hubert Higgins, "Humaniculture," New York (Stokes), 1906; and Irving Fisher, "The Effect of Diet on Endurance," publications of Yale University, Transactions of the Connecticut Academy of Arts and Sciences, 1907.

A great deal has been written as to what foods are best. There exist various dietetic cults, such as vegetarians and fruitarians, raw-food advocates, etc. The question of what foods are ideally best is too large a one to be entered upon here. The evidence seems to point to a general conclusion that no hard-and-fast rule of exclusion is advisable, and that the value of different foods varies with the individual and with his activity, locality, physical condition, etc. His own instinct, restored and educated by avoiding the pernicious habit of food bolting, may be made a truer guide than the wisest physician or physiologist. The same rule applies to the amount of food to be eaten, as well as to the proportions of protein, fat, carbohydrates,[a] and mineral salts. Food bolting often leads to overeating.

It should be noted that the conclusions of Chittenden and others are not in favor of a vegetarian régime, but of a low protein régime, whether vegetarian, lacto-vegetarian, or with flesh foods in moderation. The main point is moderation of the foods highest in protein, such as the whites of eggs and meats (especially lean meats).

It would seem that the safest course for the average man is to follow the appetite, simply guiding it toward a low protein diet by thorough mastication, and by giving the benefit of the doubt to foods low in protein. A reduction in the use of meat will increase, and probably cheapen, our national food supply. The raising of cattle requires much more land than the raising of cereals, fruits, nuts, and vegetables yielding the same amount of food value. As this will be a most important economic problem during the next hundred years, the question of the character of our food supply should be most carefully considered in the study of the conservation of natural resources. It is interesting to note, in this connection, that during the last century the consumption of flesh foods in the United States has considerably decreased.[b]

The subject of auto-intoxication as a consequence of excessive protein has already been mentioned.[c] To avoid auto-intoxication the putrefactive bacteria may be neutralized by lactic bacilli, such as are contained in sour milk. Another preventive is regular attention to thorough evacuation.

Diseased foods are, needless to say, dangerous. Oysters are often planted in waters polluted with sewage, with the result that epidemics of typhoid fever have been traced to their consumption.

The housewife must be the guardian of the family in these respects, and in the cooking, preparation, and arranging of food generally. These now constitute "domestic science," which is justly winning recognition as one of the most potent of all hygienic agencies. When the kitchen becomes a scientifically conducted laboratory we shall have the basis of a sound "home economics."

---

[a] For a short method of measuring these magnitudes, see Irving Fisher, "A New Method of Indicating Food Values," American Journal of Physiology, Vol. XV, No. V, April 2, 1906; and for its practical application see "A Graphic Method in Practical Dietetics," Journal American Medical Association, Vol. XLVIII, April 20, 1907. See also, "Statistics of Diet in Consumptive Sanatoria," American Journal Medical Sciences, September, 1906.

[b] See G. K. Holmes, "Meat Supply and Surplus," Bureau of Statistics, Department of Agriculture, Bulletin 55, 1907, p. 47. Mr. Holmes finds that the consumption of dressed meat per capita in the United States decreased between 1840 and 1900, 40 per cent, and between 1890 and 1900, 25 per cent.

[c] Supra, Chap. V. See also Herter's "Common Infection of the Digestive Tract."

SECTION 5.—*Drug habits.*

It would scarcely be an exaggeration to say that the first rule of hygiene is to avoid poisons. Poisons may be generated within us or ingested from without.

Drug habits take numerous forms, and they are more prevalent than most persons realize. The commonest form of intoxication is alcoholic.[a] It is interesting to observe the change which has come about in the attitude of scientists toward alcohol. From having enjoyed a high place in materia medica, it is in danger of being completely discredited.[b] So far as its habitual use is concerned the only question which remains in debate is whether in minute quantities it may be innocuous or even beneficial. In any except minute quantities it has been shown to be injurious.

> It lowers the resistance of the white corpuscles, which are the natural defenders of the body. Although the phagocytes belong to the most resistant elements of our body, yet it is not safe to count on their insensibility toward poisons. It is well known that persons who indulge too freely in alcohol show far less resistance to infectious diseases than abstemious individuals.[c]

Here is the gravest indictment that may be brought against the abuse of alcohol. It is not, however, the only one. The relation of drinking to insanity,[d] peripheral neuritis, Bright's disease, cirrhosis of the liver, inflammation of the stomach, arterioschlerosis (a most common cause of apoplexy),[e] tuberculosis;[f] to crime in all its forms,[g] and to all the possibilities incident to the hereditary transmission of a weakened organism[h] has been pointed out. If personal hygiene is a duty, it is the duty of every man to recognize the danger from alcohol to himself and to his progeny yet unborn. Instead of copying the habits of others, he may consider the responsibility of causing others to copy his.

A subcommittee of the Committee of Fifty for the investigation of the liquor problem published in 1899 a volume on the economic aspects of the problem. The investigation covered a period of about three years and was carried on under the general direction of Prof. Henry W. Farnam, of Yale University. The general conclusions of this investigation were that of the poverty which came under the notice of the charity organization societies about 25 per cent could be traced directly or indirectly to the use of liquor; of the poverty found in almshouses, about 37 per cent. In the investigation of crime, the conclusion was reached that liquor was a first cause in 31 per cent of the criminals studied, and that it entered in as a cause, directly or indirectly, in 50 per cent.

---

[a] For a discussion of the physiological effects of alcohol, see Physiological Aspects of the Liquor Problem, investigations made under the direction of W. O. Atwater, John S. Billings, H. P. Bowditch, R. H. Chittenden, and W. H. Welch, subcommittee of the Committee of Fifty; New York, Houghton & Mifflin, 1903, 2 vols.; and The Liquor Problem, a Summary of Investigations Conducted by the Committee of Fifty, 1893-1903, by John S. Billings, Charles W. Eliot, Henry W. Farnam, Jacob L. Greene, and Francis G. Peabody, 1905.

[b] The rôle of alcohol as a predisposing cause of disease has already been noted. It has long been known that drunkards have a very slim chance of recovery when attacked by pneumonia, and it is noted also that the mortality among moderate drinkers is higher than among total abstainers. This fact has long been known to life-insurance companies as holding good for many diseases other than pneumonia. Osler: Modern Medicine, Vol. II, p. 628.

[d] See "Twenty-sixth Annual Report of Massachusetts Bureau of Labor," 1905.

[e] Ditman, loc. cit., p. 47.

[f] See John Huber, M. D., "Predisposition to tuberculosis," The Medical News, December 26, 1903, p. 12. Also reports of Phipps Institute, Philadelphia.

[g] See Boies's various works, the "Reports of the Committee of Fifty," and Report of the Massachusetts Bureau of Labor Statistics, 1895.

[h] See Henry Smith Williams, M. D., "Alcohol and the Individual," McClure's Magazine, October, 1908, pp. 704-712.

The investigation made by the Massachusetts bureau of statistics of labor in 1895 indicated the following percentages due to alcoholism:

	Per cent.
Crime	84.41
Pauperism	48
Insanity	35

Several English life-insurance companies—the Sceptre, the United Kingdom, and General Provident and others—have found by their statistics, running over forty years, that abstainers have a death rate about 23 per cent lower than nonabstainers.[a] Since the figures of the Mutual Life Insurance Company of New York[b] give the same advantage to American abstainers (23 per cent lower death rate), it seems fair to take the available computations of the English life insurance companies as a basis for estimating the saving of life that would result in the United States if individuals should decide to give up the use of alcohol. It should be remembered, however, that the favorable figure of total abstainers is partly due to the fact that as a class they practice personal hygiene in all its forms.

A basis for computing the sickness that might be saved by total abstinence is furnished by comparison between the sick rates of abstaining and nonabstaining societies, made by Mr. H. Dillon Gouge, public actuary of South Australia, in 1892. He found that the average weeks of sickness in three societies of abstainers was 1.248; in three societies of nonabstainers the average weeks of sickness was 2.317 (lacking only one-sixth of being twice as much).

Absinthe in France has become almost as clearly [illegible]ause of national degeneration as opium in China. Fortunately for our own country there exists here a more determined effort than in most, if not all other nations, to be rid of alcoholism. The movement has been formidable enough to arouse anxiety among those whose capital is invested in breweries, distilleries, and saloons. The movement reaches its maximum momentum in the west and the south of the United States. It is significant of the rapid change of sentiment in regard to the liquor question that physiologists, physicians, educators, and publicists are now becoming so thoroughly impressed with the importance of suppressing the evils of alcohol.

The younger members of the Kaiser's family in Germany are opposed to the German habits in regard to the use of alcohol, and the son of the Kaiser chose for his university one where there was less drinking than at other universities. President Eliot, of Harvard University, has recently taken a strong position against the use of alcohol, even "in moderation."

[b] "Effect of Total Abstinence on the Death Rate," by Joel G. Van Cise, actuary of the Equitable Life Assurance Company of the United States.

Another common, though less injurious, source of self-poisoning is tobacco, which is known to stunt the growth of the young, to lead to sluggishness and weakened hearts ("tobacco hearts"), and to cause dyspepsia and neurasthenia.

Snuff taking has almost disappeared as a habit in this country. Chewing tobacco is still common, though no longer defended by hygienists. "Inhaling" is more common, though also usually condemned on grounds of health. Smoking shows no signs, as yet, of decreasing. In moderation it may not be injurious. There are no definite proofs on either side. But smokers are seldom moderate.

Doctor Seaver, of the Yale Gymnasium, found that of the 187 men in the class of 1891, Yale College, those not using tobacco during the college course had gained over the users of tobacco in weight 32 per cent, in height 29 per cent, in growth of chest 19 per cent, and in lung capacity 66 per cent.[a]

Similar returns for the Amherst graduating class of 1891 showed a gain by the nonusers of tobacco of 24 per cent in weight, of 37 per cent in height, and of 42 per cent in growth of chest. In lung capacity the tobacco users had lost 2 cubic inches of air space, while the nonusers had gained 6⅓ cubic inches.

The somewhat injurious effect of tea, coffee, and condiments, though less than many other evils, should be included in any list of the imperfections in respect to hygiene of existing habits of life.

SECTION 6.—*Activity hygiene.*

Only a generation ago there were scarcely any gymnasia in this country, but to-day the importance of regular exercise and bathing is recognized by everyone. This is far from saying, however, that this important method of conserving our vital resources has more than begun to be exploited.

First, the bath for the well-to-do, and, latterly, the public baths for the poor, have given all an opportunity to obtain the cleansing and healing agency of water. And in recent years the application of baths has become a science.[b]

Baths may be used as social agents. Judge Ben. B. Lindsey, of the Denver juvenile court, insists that every child must take a bath before appearing in the court room. Neutral baths, i. e., baths regulated to the temperature of the body, have been found valuable in relaxing the nerves of the body, and even in the treatment of mental disease.

---

[a] Doctor Anderson, of the Yale Gymnasium, finds similar results. He also points out a statistical pitfall into which some investigators have fallen. This is the common statistical fallacy of selection. There are two great groups of college sudents, roughly distinguished as athletes and scholarship men. (See Doctor Sargent, "Physique of scholars, athletes, and the average student," Popular Science Monthly, September, 1908.) Smoking is more common in the former group. They are not athletes because they smoke, but smoke because they are athletes. The raw figures of smokers and nonsmokers usually show that the smokers have better physical development, but if we compare the smoking athletes with the nonsmoking athletes and the smoking scholarship men with the nonsmoking scholarship men the results are quite different. For similar statistical fallacies, due to failure to subgroup properly, see Mayo-Smith, "Statistics and Sociology," Macmillan, 1895.

[b] See J. H. Kellogg, M. D., "Rational Hydrotherapy," Philadelphia, 1904.

As to exercise, a healthy organism must call into play every function daily, both mental and physical. One of the evils of the division of labor which civilization has brought is that the sedentary worker does not have enough physical exercise, but too much mental exercise, while the situation is just the opposite in the case of the workingman.

A well-known physical director, now nearly 50 years old, writes me that he has this year taken up systematic physical training, which he has neglected for several years because of pressure of work. As a result his weight has risen, his chest and arm girths have increased, while his waist girth has decreased, and he is conscious of decided improvement in memory and in sleep. This instance is cited as an example of the physical development possible in a man of middle age.

In its bearing on exercise, the growth of modern athletics and its effects on the physical ideals of men and women is to be welcomed. The revival of the Olympian games and the spread of popular participation in such outdoor sports as golf, tennis, boating, and horseback riding have all had their share in building up a new health ideal. Thus we are getting away from the mediæval idea of mortification of the flesh and approaching more closely the Greek conception of a beautiful body as the covering for a beautiful soul. The Greeks lifted their sports to a higher level than ours by surrounding them with imagination and making them a training in æsthetics as well as in physical excellence.[a] The American idea is at present too closely connected with mere winning, and not enough with development. In the past the physical athlete has been too much associated with the pugilist, and has been looked down upon as having merely brute strength. The intellectual type, on the other hand, has been content wholly to neglect bodily development.

In the last three years considerable evidence has accumulated to show that the sitting posture of the sedentary man tends sooner or later to produce nervous prostration, and that the ordinary chair invites to this effect by producing a bent attitude, both in the forward direction and in the shoulders. The effect of the former is to tax the splanchnic nerves and congest the portal circulation. The splanchnic area, which is enormous, is a sort of overflow tank for the blood. If the muscles of this area are allowed to relax through improper position in standing or sitting, the result is the stagnation of the blood in the abdomen, and this in turn results in a vicious circle of evil effects. Since much of our life is spent in chairs, this fact is of no small importance. Improperly made school chairs and unhygienic habits of sitting in them may start off millions of young lives with round shoulders, curved spines, and the later effects of portal congestion.

Exercise of mind does not simply mean exercise of intellect. The emotions and the will are equally a part of a well-developed healthy man. Late in life Darwin had occasion to lament the fact that his emotional capacity had become cramped because he had exercised his mind in his own branch of work to the exclusion of other things. Whatever our ideas of theology or religion are, it is true that we all ought to have a spiritual sense. Some men lack this spiritual sense and are incapable of understanding the spiritual experience of others. "For toil without purposeful and occupied leisure is unfilled purpose, a process arrested midway."[a] Worry and fear are unhealthy. Hope, courage, enjoyment, and an optimistic attitude generally are healthy.[b]

---

[a] See G. L. Dickinson: "The Greek View of Life," New York (McClure, Phillips), 1906, pp. 131–134.

The ordinary workingman works two or three hours too much every day. Nearly every man overworks himself, takes insufficient rest and recreation, and worst of all, cuts off his normal portion of sleep. Fatigue ought to be "avoided like poison," because, physiologically, it is really poison. Worry, fear, and anger also produce poisons harmful to the human body. This is suggested at least by the effect upon a nursing infant of violent paroxysms of anger, or periods of intense fear or anxiety on the part of its mother. The intense exhaustion which follows such paroxysms is another case in point.

An animal lives a much more healthy life than the average man, because an animal follows instinct, while a man to a large extent endeavors to substitute for his instincts rules which are very often false. One of the instincts constantly disregarded by man is that which finds its expression in fatigue. The ordinary man working for some one else is compelled to toil beyond the fatigue limit; and, on the other hand, if a man is in business for himself, he does the same thing of his own will. Although no one knows what sleep is, it serves, according to the best theory, to eliminate poisons and to rebuild tissue. With rest is closely associated recreation. Play practices the power of a child's mind, while contest among children develops self-control.[c] Similarly, adults are rested by play or recreation, their minds and bodies are relaxed, while their contests of mimic warfare develop their powers of will and effort.

SECTION 7.—*Sex hygiene.*

One element in personal hygiene concerns the sex relation. This can not be treated under other heads, for the sex relation is so purely a personal and individual one. From its normal utilization there is little to fear, but from the effects of illegitimate sexual practices the world suffers enormous yearly losses. It is hardly possible to have promiscuous sex relations out of wedlock without contracting one or the other of the serious venereal diseases. The best authorities report that "every prostitute is diseased some of the time and some prostitutes are diseased all of the time."

One disease, syphilis, infects the blood and therewith all parts of the body. For months after infection with this disease the individual may communicate it by a kiss as well as by cohabitation; and articles moistened by his secretions—towels, drinking glasses, pipes, etc.—may also convey the infection. While under proper treatment the disease is not always dangerous to life in the earlier years, yet the possibilities of transmitting the contagion should forbid marriage for at least three years.

Sidis: "The Psychology of Suggestion," New York (Appleton), 1899, 386 pp. Schofield: "The Force of Mind, or the Mental Factor in Medicine," London (Churchill), 1902, 309 pp.

[c] See President G. Stanley Hall: "Play and Dancing for Adolescents," Independent, reprinted in "Mind and Body," Vol. XIV, 1907, pp. 43-48.

The most serious results of syphilis, some authorities say, may appear years after its acquisition, when the individual has been lulled into a false sense of security by long freedom from its manifestations and considers himself cured. Many cases are practically incurable. Some are fatal in spite of treatment. It may attack any organ of the body. Among the many diseases to which it may lead are apoplexy, paralysis, insanity, and locomotor ataxia; and these often appear after the man has acquired a family that is dependent upon him for support.

The leading insurance companies refuse to insure the life of a syphilitic person for four or five years after the disease was contracted, and then only upon special terms, for their records prove that syphilis shortens life.

That the syphilitic parent may transmit the disease to his offspring is common knowledge. Some of his children are destroyed by the inherited disease before birth; others are born to a brief and sickly span of life; others attain maturity, seriously handicapped in the race of life by a burden of ill health, incapacity, and misery produced by the inherited taint, while still others escape these evil effects.[a]

Forel, in Die Sexuelle Frage, shows that even Weissman does not deny the possibility of poisoning the germ cell and so transmitting some "acquired characteristics," as in alcoholism and venereal poisoning. One of the saddest facts in both cases is that the parent may escape and the children reap the results in insanity, tendency to consumption, and prostitution.

Another disease—

> Gonorrhea, while usually cured without apparent loss of health, has always serious possibilities; it kills about 1 in 200; it impairs the sexual power and fertility of a much larger number; it often produces urethral strictures, which later may cause loss of life.[a]
>
> The persistence of gonorrhea in the deeper parts long after it is outwardly cured leads to the unsuspected communication of the disease to women with whom the individual may cohabit. Much of the surgery performed upon women has been rendered necessary by gonorrhea contracted from the husband. Should she while infected with this disease give birth to a child, the baby's eyes may be attacked by the infection, sometimes with immediate loss of sight. Probably 25 per cent [b] of the blindness of children is thus caused.

Dr. Prince A. Morrow says:

> This social danger comes from frequent introductions of these diseases into marriage. The frequency of marital contamination does not admit of exact mathematical expression, as both social sentiment and professional ethics unite to cover up and conceal it. Possibly 10 per cent of men who marry infect their wives with venereal disease.

---

[a] Circular No. 2. "Self-protection," Chicago Society of Social Hygiene, pp. 7–8.

[b] The average of a great many statistics shows that one-fourth of all blind persons owe their affliction to the effects of opthalmia of the new born." Chas. H. May, M. D., ophthalmic and aural surgeon, New York, Transactions of American Societies of Sanitary and Moral Prophylaxis, Vol. II, 1908.

The report of the Committee of Seven (New York) shows that in private practice nearly 30 per cent of venereally infected women were contaminated by their husbands. The report of the Committee on Sanitary and Moral Prophylaxis (Baltimore) shows that nearly 40 per cent of the infections in women seen in private practice were communicated in married life. "My own observations at the New York Hospital, extending over a period of several years, would indicate that fully 70 per cent of all women who came there for treatment of syphilis were respectable married women who had been infected by their husbands.[a]

Observation shows that gonorrhea is markedly intensified in virulence and danger to the woman in fulfilling the functions for which marriage was instituted. Pregnancy and childbearing open the way for germs. One of the most constant effects of gonorrhea in women is permanent and irremediable sterility. Fifty per cent of gonorrheally infected women become absolutely sterile, and a still larger percentage sterile after the first child is born (one-child sterility). Noeggerath found in 81 gonorrheal women 49 entirely sterile. In 80 sterile marriages Kehrer found 45 caused by inflammatory changes of gonorrheal origin. It is estimated that the husband is directly responsible for 20 to 25 per cent of sterility from his inability to procreate as the result of gonorrhea. In addition the husband, though not sterile himself, may infect his wife, rendering her sterile. The disease is ultimately responsible for about 70 to 75 per cent of all sterility in married life, which is not of choice, but of incapacity. Lier-Ascher's careful statistics place this proportion at 71.2 per cent. These figures relate to absolute sterility. The chief social danger of gonorrhea as a depopulating factor is the creation of secondary sterility, or what has been expressively termed "one-child sterility." The large percentage of marriages in which one child represents the total fecundity of the family justifies the conclusion that this sterility is in many cases not of choice, but of procreative capacity extinguished by gonorrhea.[b]

In addition, the inflammation set up in the maternal organs may render the mother a permanent invalid or compel her to submit to a mutilating operation to save her life.

Gynecologists furnish statistical evidence showing that 80 per cent of the deaths due to inflammatory diseases peculiar to women[b] and about 70 per cent[c] of all the work done by specialists for diseases of women is caused by gonorrhea.

In addition to the effect of a low protein diet on endurance, already discussed, and on general health, its relation to the sexual life should be mentioned. Experiments on this subject seem to show that excessive meat eating and excessive protein intake tend to irritate the sexual organs and to produce abnormal sexual desire just as they do a desire for alcoholic stimulation. This fact is of importance in preventing secret vice among the young.

---

[a] Morrow, Social Diseases and Marriage, Philadelphia (Lea), 1904.

[b] In report of special committee of the American Medical Association, 1901, Hunniston says: "Ninety per cent of inflammatory troubles of maternal organs are attributable to gonorrhea." Price says: "That in over 1,000 operations for pelvic trouble 95 per cent were attributable to this infection." Another authority gives a percentage of 75.

[c] Address of Doctor Cleveland, president of American Gynecological Society, at National Congress of American Physicians and Surgeons, Washington, 1907.

Thanks to the efforts of a few farsighted men like Dr. Prince A. Morrow, Prof. C. R. Henderson, and Mr. Edward Bok, these subjects are being given some of the publicity they deserve. Reticence on these subjects is justified only so far as it makes for youthful innocence. But ignorance is not innocence; on the contrary it is the surest road to guilt.

SECTION 8.—*Personal hygiene in general.*

Personal hygiene is only beginning to be generally exploited. Most persons leave their health to be attended to by physicians and health officers, just as many people leave their religion in the hands of a priest or clergyman. So far as practiced at all, personal hygiene has been confined chiefly to invalids and athletes. Even by them it is usually practiced to tide over an illness or to prepare for a contest. But it is manifest destiny that a wise economy of vitality will sooner or later be practiced. Waste of vital resources is as irrational as waste of natural resources. Neither is inexhaustible and both must be conserved. Thoughtlessness and ignorance are the reasons for the appalling waste of both now going on. Even people who do not defiantly abuse their strength by definite excesses are liable to waste it gradually. Slightly unhygienic habits grow, and their effects are doubtless cumulative. It is well known that even a so-called "ventilated house," if lived in long enough without sufficient outdoor life, may induce tuberculosis. This must be through the repetition of an infinitesimal injury produced through each respiration eighteen times a minute for twenty-four hours a day for half a lifetime.

So with the use of food preservatives. Food manufacturers have laid much emphasis on the fact that preservatives are "harmless" because used in small quantities, but Doctor Wiley has raised the question whether even very small quantities of these preservatives, if used continuously for a sufficient length of time, are not injurious. The same applies to the repetition of preservatives in a large number of different foods. If only one particular food contained a preservative, the effect would be relatively negligible; but as one food after another has become adulterated, the human stomach is made the daily receptacle of many times the "harmless" amount in any one particular food. The obstacles to hygiene which have accumulated with civilization are almost as numerous and as small as the barnacles which impede a ship. To remove them is in large part to "return to nature." Many of the inventions of which civilization boasts have had an unhygienic side. The invention of houses has made it possible for mankind to spread all over the globe, but it is responsible for tuberculosis, especially after glass was devised, which while letting in the light keeps out the air. The invention of cooking and preparing foods has widened the variety of man's diet, but has led to the decay of his teeth.[a] The invention of the alphabet and printing has made possible the accumulation of knowledge, but it has produced eye strain with all its attendant evils. The invention of chairs has added to human convenience, but has led to spinal curvature and abdominal congestion. The device of a division of labor has added to wealth, but has destroyed the normal balance of mental and physical work, recreation, and rest. Similar fault may be found with clothing, especially corsets, shoes, and hats, and with numerous other contrivances. Yet it would be foolish, even if it were possible, to attempt to "return to nature" in the sense of abolishing civilization. We must not go backward, but forward. The cure for eye strain is not in disregarding the invention of reading, but in introducing the invention of glasses. The cure for tuberculosis is not in the destruction of houses, but in devices for ventilation. It is a little knowledge that is dangerous. Civilization can, with fuller knowledge, bring its own cure and make the "kingdom of man" far larger, even in respect to hygienic conditions, than "nature" people can ever dream of.

---

[a] See Ottofy, "The Teeth of the Igorots," Dental Cosmos, July, 1908, where it is shown, statistically speaking, that the teeth of Americans are "ten times as bad as those of the Igorots," while the civilized Filipinos have teeth as bad as those of Americans.

Unhygienic customs and fashions are exceedingly slow to yield, but they do yield in the end. It should be the part of intelligent men to lead in hygienic reform, not by intolerant and impatient abuse of their fellow-men, but by the quiet force of example. The intolerant and impatient reformer does incalculable harm, for he takes no account of that subtle perversity of human nature which resents his interference. Equally harmful is the man who seeks only to imitate the crowd, who condones the vices of his time and country.

But we must always bear in mind what has been called the "psychology of the crowd." Tarde, Le Bon, Baldwin, Ross, and others have shown that society is largely ruled by customs which grow out of imitation. In order that any social custom shall be changed, initiative is necessary. The upper classes should take the lead, for any reform will spread many times more quickly when the initiative comes from above than when it comes from below. Western civilization has made its marvelously rapid progress in Japan for the simple reason that the Mikado approved, and marvelously slow progress in China for the simple reason that the Empress disapproved.

We find the same principle at work in the progress of medicine. Hydrotherapy originated with a peasant and required three centuries to come into vogue. The use of sour milk, on the other hand, has been advocated only during the last two or three years, but the initiative came from Metchnikoff, one of the foremost of medical scientists. The consequence is that the so-called "sour-milk craze" has already led to great industries and affected the business of groceries, soda-water fountains, and even liquor saloons.

The change constituting hygienic reform will be brought about most rapidly by the influences on the young. If children in their homes and schools are given proper models for imitation, the public opinion which they will form may make a revolution in a single generation. Anyone who realizes the almost resistless force of the principle of imitation, especially when applied to children, will receive a new sense of the responsibility he takes in setting an example to the young. There are three classes in particular on whom the responsibility is heavy—teachers, physicians, and parents. If they wish the child to be free from the cigarette habit, they must sacrifice the cigar and pipe habit, even though it be true that cigars and pipes are not injurious to adults. They may believe this, but the children will not. The same principle applies to other and more serious infractions of the laws of health. It is probably through the love of the next generation, rather than through any selfish care for the present, that men and women now living will take the most pains to secure the best results in bringing about the change in living conditions for which every hygienist hopes.

CHAPTER X.—*Are hygienic measures eugenic?*

SECTION 1.—*Prolongation of weak lives.*

We have discussed two factors which cooperate to produce vitality, namely, heredity and hygiene; and two corresponding methods of improving vitality, namely, by utilizing a possible science of eugenics on the one hand and by utilizing the existing science of hygiene on the other. The question now arises, Are these two methods in conflict with each other? It is charged that hygiene prolongs the lives of unfit and defective classes. We have already seen that in Indiana, institutional care of the insane has prolonged the average insane lifetime by some eight years. Referring to the insane, Dr. Charles Dana says:

> For twenty-five years the explanation of this increase in statistics of insanity has been that more cases were observed and more victims kept in institutions than formerly; and this is still the explanation. It is my opinion, however, that the increase is a real one, and it is one to be expected not only from the strenuousness of modern life and increase of city population, but also, because more feeble children are nursed to maturity and more invalid adolescents are kept alive to propagate weakly constitutions or to fall victims themselves to alienation, the period of life susceptible to insanity is longer.
>
> A fourth of the cases of insanity is due to so-called "moral causes:" Emotional strain, shocks, and vicious indulgences. But moral causes are not sufficient to cause insanity if the individual has a strong constitution. Insanity is increased in part, then, because we are saving too many lives by the careful regulations of our health boards. Hence, those who are working so enthusiastically and nobly and successfully in preventing disease achieve results which carry serious responsibilities for the State.[a]

It is true that we prolong the lives of the insane and defective classes, and that they thus make a greater burden on society. We should see to it that certain of these classes are not permitted to propagate their kind. This point has been explained in Chapter VI.

It is further claimed that infant mortality is but the operation of natural selection and should not be interfered with if we are to keep up the vital power of the race. Preventive medicine has certainly prolonged the lives of infants or, at any rate, of children in general.[b] But has this weakened the race? It is pointed out that the mortality later in life has not decreased, and that in some cases it has even tended to increase. But this fact can be explained in either of two ways. One is on the hypothesis of the extension of the lives of weak infants. The other is on the hypothesis of the comparative neglect of hygiene among adults. It is surprising that this latter alternative has not been given due consideration.

---

[a] "Psychiatry in its relation to the other sciences," by Charles L. Dana, M. D., before the section on psychiatry at the International Congress of Arts and Science, at St. Louis, September, 1904. See also Janus in Modern Life, by W. M. Flinders Petri, New York (Putnam), 1907.

[b] See Edwin Graham, "Infant mortality," Journal American Medical Association, September 26, 1908; also Edward B. Phelps, "Statistical study of infant mortality," Quarterly Publications American Statistical Association, September, 1908. Mr. Phelps shows that infant mortality has declined less than is commonly believed, and that its apparent decline is often due to inaccurate and misleading statistics.

Every detail of infant life has latterly been made the subject of special study, and every mother of common intelligence has tried to learn and to apply the results of that study. The times of the baby's meals, the quantity of its feeding, the modification and sterilization of cow's milk, the hours of sleep, the ventilation of sleeping rooms, and other innumerable details are now attended to with scrupulous care. The change in these respects, even within the memory of most persons now living, is striking. The children have reaped the reward. But no corresponding change has taken place in the habits of the adult population. Many families buy one grade of milk for the babies, and another cheaper grade for the rest of the family. This they regard as "economy." Parents require their children to keep regular and suitable hours for sleep, but "owl it" themselves. They will keep their children out of doors, and send them into the country, but subject themselves to the dust, smoke, and close air of the workroom and places of business. They will not allow their children to use alcohol or tobacco, or even tea or coffee, much less opium, chloral, or other habit-forming drugs, but they take these themselves as a matter of course. They are now insisting on playgrounds for children, but their own amusements are sought in the unhygienic theater, or maybe in the saloon or immoral resort. The child is protected on all sides, with the result that he sometimes lives almost an ideal animal life, with its due proportion of amusement, exercise, rest, and sleep. The parents themselves are tied down to drudgery, overwork, worry, and long hours. The difference, when we reflect upon it, is startling. We make hygiene paramount for our children; for ourselves we neglect it totally, partly from the idea of sacrificing ourselves for the sake of our children, partly from necessity, real or imagined, and partly from the thraldom of habit already formed. With such a contrast between the recent improvement of hygiene in childhood and the lack of improvement in middle life, one need not wonder that the mortality of one period has improved and that of the other has not. We do not need to invoke the aid of the theory that weak lives have been more prolonged than strong lives. The moral is that hygiene should not stop in childhood. It is natural and proper, however, that the first attempt to apply hygienic knowledge should begin with children. It is through children that new ideas usually make their way into custom. "You can't teach an old dog new tricks." Grown persons have habits already formed, and when once a habit is formed it is difficult to change it.

Habits of living among adults have even grown worse in some respects. Observing practitioners comment on the increasing nervous tension in modern life. The rush of the railway train, the telephone, the elevator are at once an outgrowth and an excitant of this increased tension. They are life's pace makers, and the pace is ever quickened. The health officer of New York City attributes to this severer strain the increase of heart and nervous diseases. It would be interesting to know the relative prevalence of adult diseases under conditions of reposeful and exciting surroundings and occupations, but I know of no investigation on this phase of the subject.

While this report was being written the recent figures from Great Britain came to hand. They show that the tendency of the death rates among the later ages to increase seems to have given place to a slightly opposite tendency. The expectation of life at ages 40, 60, and 80 during the decade of 1891–1900 has a little more than held its own as compared with the previous decade.

SECTION 2.—*Children's diseases impair both fit and unfit.*

Another point needs emphasis. When it is said that the lives of weak infants are prolonged it is commonly overlooked that the same causes also prolong the lives of the strong, and, reversely, that unhygienic conditions which tend to exterminate the weak tend also to shorten the lives of the strong. Bad hygiene is merely a common handicap for all classes. The burden of proof is upon those who claim that it has a differential effect and increases the process of weeding out the unfit. This weeding-out process goes on whether there is a great or a small obstruction to overcome. Bad air and children's epidemics are the common environment of all. While this must produce a greater mortality, it remains to be shown that it would be more selective.

That a high infant mortality does not tend to lengthen life, but rather to stunt all life, would seem to be indicated by the evidence, so far as it can be interpreted. Russia, for instance, has a high infant mortality. If the statistics are to be trusted, it is 70 per cent greater than in the United States; yet Moscow and St. Petersburg have a general mortality rate which greatly exceeds that of similar cities in this country.

It may be that the more unfavorable the struggle for existence the more rapidly will natural selection result in improved vitality. But even if this were true, it would not imply that in a more favorable environment selection would cease. And it may not be true. It may be that adversity, if too severe, will crush and injure the survivor as well as eliminate the unfit. We do not look for the best trees on the bleak mountain top, but in the genial valley. As we go up the struggle for existence increases, until even the sturdiest fail to thrive above the "timber line."

> The farmer who tries to improve his stock does not select hardships. Cold and starvation are now negligible quantities in the great ranches, and the breeds that were notable for ability to withstand them give way to varieties that may be adapted to neither emergency.[a]

Venereal diseases, hook-worm disease, malaria, and many other maladies shorten and weaken life, whether of weak or strong. Referring to the racial degeneration probably caused by malaria on the sturdy Greek, Maj. Ronald Ross said, in an address before the Oxford Medical Society, November 29, 1906:[b]

> Now what must be the effect of this ubiquitous and everlasting incubus of disease on the people of modern Greece? Remember that the malady is essentially one of infancy among the native population. Infecting the child one or two years after birth, it persecutes him until puberty with a long succession of febrile attacks. * * * Imagine the effect it would produce upon our own

---

[a] Simon N. Patten, The New Basis of Civilization, New York (Macmillan), 1907.

[b] This quotation is from Dr. L. O. Howard's report to the Conservation Commission on "Economic loss to the people of the United States through insects that carry disease."

> children here in Britain. * * * What would be the effect upon our population, especially our rural population—upon their numbers and upon the health and vigor of the survivor? It must be enormous in Greece. People often seem to think that such a plague strengthens a race by killing off the weaker individuals; but this view rests upon the unproven assumption that it is really the weaker children which can not survive. On the contrary, experience seems to show that it is the stronger blood which suffers most—the fair, northern blood which nature attempts constantly to pour into the southern lands.[a] If this be true, the effect of malaria will be constantly to resist the invigorating influx which nature has provided; and there are many facts in the history of India, Italy, and Africa which could be brought forward in support of this hypothesis. * * * In prehistoric times Greece was certainly peopled by successive waves of Aryan invaders from the north. * * * That race reached its climax of development at the time of Pericles. * * * Suddenly, however, a blight fell over all. Was it due to internecine conflict or to foreign conquest? Scarcely, for history shows that war burns and ravages, but does not annihilate. Thebes was thrice destroyed, but thrice rebuilt. Or was it due to some cause, entering furtively and gradually sapping away the energies of the race by attacking the rural population, by slaying the newborn infant, by seizing the rising generation, and especially by killing out the fair-haired descendant of the original settlers, leaving behind chiefly the more immunized and darker children of their captives, won by the sword from Asia and Africa? * * * I can not imagine Lake Kopais, in its present highly malarious condition, to have been thickly peopled by a vigorous race; nor, on looking at those wonderful figured tombstones at Athens, can I imagine that the healthy and powerful people represented upon them could have ever passed through the anæmic and "splenomegalous" infancy (to coin a word) caused by widespread malaria. Well, I venture only to suggest the hypothesis, and must leave it to scholars for confirmation or rejection. Of one thing I am confident—that causes such as malaria, dysentery, and intestinal entozoa must have modified history to a much greater extent than we conceive.

Evolution in human society is a wonderfully complex thing. Survival of the races has long been dependent on a long period of protection of children by parents, and may in future even depend on protection of other kinds.[b]

SECTION 3.—*Fitness is relative to environment.*

Whether or not degeneration is actually going on is a question for which the data are insufficient for us to form an intelligent generalization. That there are very strong forces working in that direction can not be questioned, but there are also very strong forces working in the opposite direction. In discussing degeneration, one point must be borne in mind which has often been forgotten by writers on the subject. Man's fitness to live is relative to the environment in which he is to live. If muscular strength decreases, it is not a sign of degeneration, provided muscular strength is no longer needed. One does not speak of hothouse grapes as degenerates. They doubtless lack the hardy characteristics of wild grapes, but these characteristics are not needed in a hothouse.

If it should prove true that in some directions humanitarian impulses betray us into favoring the survival of the unfit and their perpetuation in the next generation, such shortsighted kindness must be checked. But all the dangers of perpetuating vital weaknesses can be avoided if proper health ideals are maintained. For when such health ideals become a national possession fewer weak infants will be born into the world. This will come about in three ways: First, marriage and "sterilization" laws will reduce the number of marriages of degenerates. Secondly, parents will be more careful of transmitting disease or weakness to their offspring. There is strong reason to believe that inheritance depends largely upon the physical condition of both parents at the time of conception. If at such a time either parent, or both parents, are in a state of intoxication or sufferers from venereal disease, this lack of hygiene on their part will affect the heredity of the offspring. Immorality, which practically means lack of sex hygiene, never strengthened a race; on the contrary it has been the most potent cause of race extinction (of the Hawaiians, Indians, negroes, and others).[a] Thirdly, the influence of higher ideals of health and vitality will tend both to restore the attraction of a strong and beautiful physique to its rightful place among the various attractions which lead to marriage, and to lessen the allurements of such extraneous attractions as wealth.

---

[a] Physicians maintain that some diseases, especially typhoid fever and pneumonia, are more apt to attack the strong than the weak.

Part IV.—RESULTS OF CONSERVING LIFE.

CHAPTER XI.—*Prolongation of life.*

SECTION 1.—*Life is lengthening.*

We have already seen evidence of the possibility of prolonging life: In Europe the life span is double what it is in India. The death rate of Dublin is over twice that of Amsterdam, and three times that of rural Michigan. Again, making every allowance for inaccuracies of old records, we have strong reason to believe that life is twice as long as three or four centuries ago, and modern accurate records show that it is to-day increasing more rapidly than ever. The rate at which this lengthening proceeds per century is shown in the following table, based on Chapter I.

Rate of lengthening life (in years, per century).

Country.	Periods.	Males.	Females.
England	1838-1854 to 1871-1881, or 30 years	5	9
Do.	1871-1881 to 1891-1900, or 20 years	14	16
France	1817-1831 to 1898-1903, or 76 years	10	11
Prussia	1867-1877 to 1891-1900, or 23 years	25	29
Denmark	1835-1844 to 1895-1900, or 57 years	13	15
Sweden	1816-1840 to 1891-1900, or 67 years	17	15
United States:			
Massachusetts.	1789 to 1855, or 66 years	7	
Do.	1855 to 1893-1897, or 40 years	14	
India	1881 to 1901, or 20 years	0	

From this table we observe:

First. That the rate of progress is extremely variable in different countries. It is perhaps no accident that the maximum rate obtains in Prussia, which is probably the most progressive country in the discovery and application of scientific medicine. If progress continues for a century at merely the present rate, human life in Prussia will be twenty-five to twenty-nine years longer than at present. The average rate of improvement for all the countries, excepting India, is about fifteen years per century.

Second. It is noticeable that in practically all cases the improvement is more among females than males. This is one expression of the progress which womankind is now making in all lands.

Third. This table, as well as the estimate of Professor Finkelnburg already quoted, shows that not only is the average duration of human life increasing, but that the rate of increase is also increasing. The estimate of Finkelnburg that the lengthening of life during the interval between the sixteenth century and the end of the eighteenth century was from eighteen or twenty years to a little over thirty years shows a rate of increase of about four years per century. During the following century he estimated that the life span increased from a little over thirty to thirty-eight or forty years, or about nine years per century. In the table we see that in England the length of life was increasing in the middle of the nineteenth century at a rate of from five to nine years per century, while during the last quarter it was increasing at from fourteen to sixteen years per century. In Massachusetts the imperfect data indicate that life lengthened in the first half of the eighteenth century at the rate of about seven years a century. The indication for the last part of the nineteenth century is that it increased at the rate of fourteen years per century.

We may briefly summarize chronologically the general rate of increase as follows:

Lengthening of human life per century.

	Years.
During seventeenth and eighteenth centuries	4
During first three quarters of the nineteenth century	9
Present rate in Massachusetts	14
Present rate in Europe	17
Present rate in Prussia	27

SECTION 2.—*Table showing further practicable prolongation.*

It would be surprising if the future should not witness a further lengthening of human life, and at an increasing rate. Of course there is a limit to the further increase of human life, but there is good reason to believe that the limit is still far off.

The following table[a] shows that at least fourteen years could be added to human life by the partial elimination of preventable diseases according to the stated ratios of preventability. This is equivalent to a reduction in the death rate of about 25 per cent. The table is based on the causes of death given in the census volume for mortality statistics for 1906. These causes are arranged according to the average, or rather median,[b] age at death from the disease. This median age is given in the second column. The order in this column shows at a glance the successive onslaught of, or rather fatality from, the various causes of death. The table shows the successive bombardments of disease to which human life is subject.

The third column gives the average lost "expectation of life;"[c] that is, the expectation cut off by each particular cause of death.

The fourth column represents the percentage which the deaths from each particular cause bear to the total number of deaths in 1906 in the registration area. It shows the relative importance of the different causes of death in the present death rate, but has no reference to the age at death.

The fifth column contains an estimate, made by physicians, of the ratio of preventability of deaths from each cause named.

---

[a] For detailed statement in regard to the construction of this table, see appendix to this chapter.

[b] By the "median" age at death is meant the age such that one-half of the deaths occur earlier and one-half later than this age. The "median" is a species of average, but differs from the ordinary arithmetical average. It has the great advantage of ease of computation.

[c] The "expectation" is taken from the figures of Abbott for Massachusetts, 1893–1897, and is the average of expectation of males and females. See Report State Board of Health for Massachusetts, 1898.

The items in the sixth column are found by multiplying together those in the fourth and fifth columns, and express the percentage which the preventable deaths from each cause named bears to the total number of deaths from all causes.

The seventh and last column gives the figures for which the table is constructed, namely, the amount of prolongation of life which would come about through preventing deaths according to the ratios of preventability in column 5. When it is said that a death is preventable, it is not, of course, meant that the person saved from it will never die, but merely that his death is postponed. The term "postponable" would avoid a great deal of confusion on the subject.

The principle on which the last column is constructed is simply the principle of averages. The column shows the prolongation of life which would be caused by postponing the "postponable" deaths by the amounts indicated in column 3. To illustrate this principle, suppose ten magnitudes to be averaged arithmetically, and that their average is thirty. To fix our ideas, we may suppose these ten magnitudes to be represented by ten lines drawn on a sheet of paper. It is evident that if one of these ten lines is prolonged the average of the ten will be thereby increased by exactly one-tenth of the prolongation of that one line.

Possible prolongation of life.

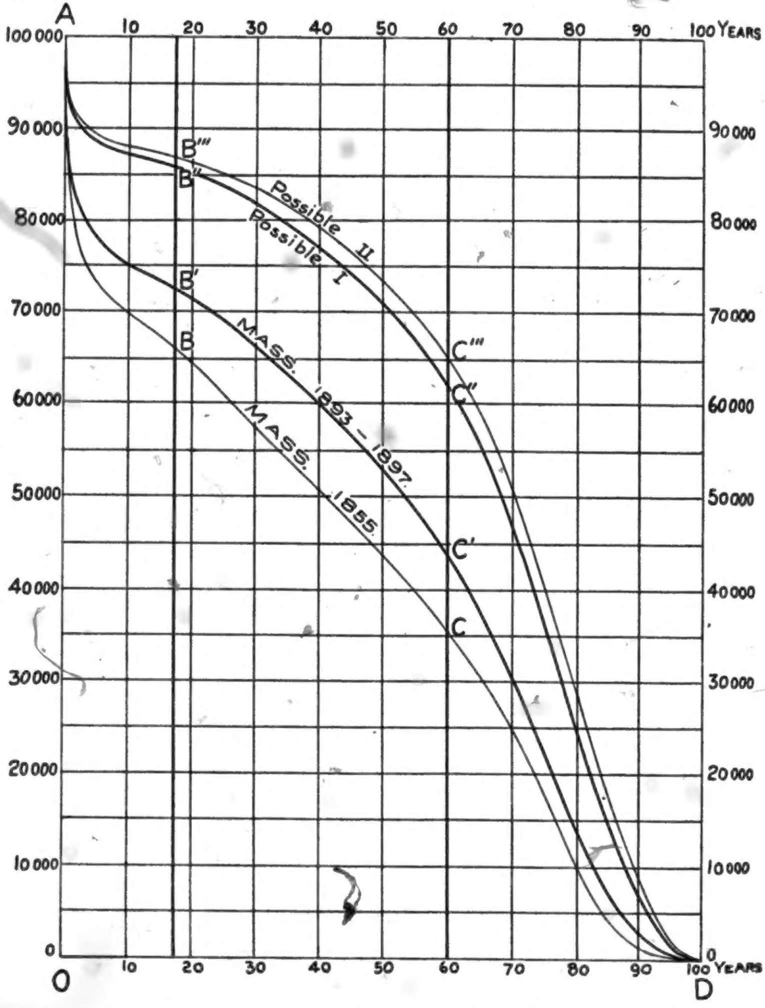
[a] Although this is the ratio of general preventability of deaths under existing conditions, the death rate, i. e., deaths in relation to population, will not in the end be affected in this ratio but by only about 25 per cent. The reason for this paradox is that deaths prevented lead to a larger population (See appendix to this chapter, section 3).

Similarly, if of the ten lines three are prolonged each a certain stated amount, or are prolonged that amount on the average, the average of the whole ten will be increased by three-tenths of this amount. Consequently, if the saved lives from typhoid fever (No. 24 in the table) are, on an average, prolonged thirty-eight years, and these saved lives represent 1.7 per cent of all lives, the average life will be prolonged by 1.7 per cent of thirty-eight years. This is 0.65 or two-thirds of a year.

All the calculations are on the assumption of expectations of life, such that the saved lives will die according to the present law of mortality. Consequently, if the table should be corrected by substituting in each case such an expectation of life as would conform to the improved mortality, the result would be an addition (2.1 years)[a] to the estimate of possible prolongation, which would therefore become 16.2 years. The résumé of the table shows that of the 14 years of possible prolongation of life 4.4 would be caused by reducing infant deaths under or near 1 year, 1.51 by reducing mortality from children's diseases, 6.82 from reducing the diseases of middle life, especially tuberculosis and typhoid, and only 1.33 by reducing the mortality of diseases the deaths from which usually come after 50 years of age.

---

[a] Best estimated graphically, as shown in appendix to this chapter.



SURVIVORSHIP CURVES, SHOWING SAFE MINIMUM IMPROVEMENT ATTAINABLE.

The table shows that seven of the 90 causes of death are responsible for over half of the shortening of life, namely, diarrhea and enteritis (No. 7), broncho-pneumonia (No. 10), meningitis (No. 13), typhoid (No. 24), tuberculosis of lungs (No. 31), violence (No. 32), and pneumonia (No. 38). These alone shorten life needlessly by more than eight years. Against these seven causes, therefore, our special efforts should be directed. Pure milk, pure water, pure air, and reasonable protection from accident are the chief means known at present. When the public makes up its mind no longer to endure impure milk, impure water, and impure air, and unreasonable dangers to life and limb, life will lengthen eight years, and probably a great deal more.

In the résumé of the table columns 4, 6, and 7 are found from the original table by simple addition. Each figure in the fifth column is found by dividing the figure in the sixth by that in the fourth.[a]

The final figure in this column, 42.3, is the same as the sum of column 6, and means that according to medical opinion 42.3 per cent of the deaths which occur under present conditions are preventable (postponable). The death rate, however, will ultimately be reduced, not in this proportion, but by about 25 per cent,[b] while the average duration of life will be increased about 33⅓ per cent.

SECTION 3.—*Diagram showing effect of prolongation at different ages.*

The whole process is best seen by means of a survivorship table, a diagram of which follows:

We have here four curves which represent the survivors in successive years from a hypothetical and representative list of 100,000 persons born. The two of these curves which should be noted are the inner two, namely, those labeled "Mass. 1893–97" and "Possible I." The former is taken, in lieu of any better statistics, as representing the existing law of mortality in the United States. The latter shows what the law of mortality would be if the ratios of preventability given in the preceding table were put in force. The curve Possible I is constructed on the supposition that all the deaths prevented or postponed subsequently occur according to the present law of mortality; that is, that expressed in the curve Mass. 1893–97.

The two remaining, or outer, curves are given merely for comparison. The lowest, marked "Mass. 1855," shows the mortality which held true in Massachusetts in that year according to the estimates of the actuary, E. B. Elliott.[c] The difference between this curve and the one above shows the number of years of life actually saved to 100,000 persons subject to the mortality of 1893–1897 instead of the mortality of 1855. The upper curve (Possible II) shows the modification in Possible I on the assumption that the saved lives, instead of following the present law of mortality (Massachusetts,

---

[a] The result is in each case a weighted average of the individual ratios of preventability for the individual causes of death.

[b] See appendix.

[c] See Proceedings of the American Association for the Advancement of Science, 1857, pp. 61, 69; also Sixteenth Registration Report, Massachusetts, 1857, p. 204.

1893–1897), follow the law of mortality represented in the curve Possible II itself.[a]

This diagram shows at a glance what improvement has been made in mortality and at what ages, and what improvement is still possible, and at what ages, according to the preventability known to be easily possible. We see that the curve, Possible I, does not drop as far in the first year of life as the curve Mass. 1893–97. This is because of the great saving of infant lives known to be possible. The years of life which would be saved to the 100,000 persons by the new hygiene are represented by the difference in area between the new curve AB″C″D and the old curve AB′C′D, from which it was constructed by applying the ratio of preventability. This area can easily be measured by a planimeter, and is found to be 1,280,000, which, divided by the 100,000 persons, means an average addition of 12.8 years to the lifetime of each person born. This result differs somewhat from the arithmetical calculation, 14.06, given in the preceding table.[b] If the upper curve be used, which assumes that the "saved" lives die not according to the old but the new mortality, the addition becomes not 12.8 but 14.9 years, as against the 16.1 computed arithmetically. We may hereafter refer to this minimum estimate of possible increase of life as, in round numbers, 15 years. The lengthening of life would be from 45 to 60, or one-third.

The diagram also shows the saving of life which actually took place between 1855 and the period 1893–1897. The area between the curves for these two periods shows that 550,000 years were saved for a supposed group of 100,000 persons, or 5.5 per person. The whole area of the new curve AB″C″D is 5,810,000, or 58.1 years per person, which is the new average duration of life, as compared with 45.3 for 1893–97 and 39.8 years for 1855. We may divide the diagram by two vertical lines drawn at the ages 17½ and 60 in order to discover what part of the added life occurs between these ages—that is, within the working period—and what parts fall on either side. The addition of 12.8 years to the lifetime of each of 100,000 persons, or 1,280,000 years of life in all, is divided into three groups, namely, the years falling in the period of preparation, 200,000; in the working period, 680,000; in the period of decline, 400,000. The following table will show the whole process:

---

[a] The method of constructing the curves Possible I and Possible II from the curve Mass. 1893–97 is by means of the ratios of preventability given in the résumé of the preceding table. See appendix.

[b] The discrepancy, 1.3 years, is due to the fact that in constructing the table, based on individual diseases, I was compelled to use for the percentages of deaths by ages (column 4) the percentages obtaining in the calendar year 1906; whereas the diagram is based on the idea of a stationary population, the distribution of the deaths being represented by the shape of the curve Mass. 1893–97. The diagramatic method is therefore more correct. The abnormal age distribution in 1906 results in making some of the figures in the last column of the table too large and some too small. In a general way, the figures for the earlier ages are too large and for the later ages too small, although the figures which are most too large are probably for ages 30 to 35. Consequently the greatest error in excess is for tuberculosis, which is possibly three-fourths of a year too large. No exact corrections are possible, and any systematic corrections, even inexact, would be very laborious. This would correspond to the elaborate actuarial calculations of Hayward in England and Glover in the United States. See Hayward "On the Construction of Life Tables and on Their Application, etc." Haydock and J. W. Glover, "A Study of Tuberculosis in the United States," Journal of Michigan State Medical Society, February, 1909.

	Preparatory period (ages 0-17½).		Working period of life (17½-60).		Period of decline (60 and beyond).		Total.	
	Years of life.	Per cent of total.	Years.	Per cent.	Years.	Per cent.	Years.	Per cent.
Mass. 1855	12.6	32	21.9	55	5.3	13	39.8	100
Mass. 1893-97	13.5	30	25.0	55	6.8	15	45.3	100
Possible I	15.4	26	31.8	55	10.9	19	58.1	100

These figures show that in 1855 the average person born lived only 12.6 years of the 17½ years in the period of preparation for life. In 1893–97 he lived 13.5 years. If modern hygiene were applied according to the ratios of the assigned preventability, the figure would then be 15.4 years actually lived out of the 17½. Of the working period of 42½ years (17½–60, the average man living under the mortality of 1855 had only about half, or 21.9 years; under the mortality of 1893–97 he had 25.0. and under the "Possible I" mortality he would have 31.8 years.

In percentage the years in the working period remain 55 per cent of the total life in all cases. This assumes that with the prolongation of life the limits of the working period remain 17½ and 60. Since the prolongation of life carries with it a postponement of the age of disability, it follows that the proportion of working life would actually increase.[a]

It will be seen in comparing the curves on the diagram that the change wrought in the character of the mortality curve by the new hygiene simply continues the change already in progress. The family resemblance between all four curves is striking.

SECTION 4.—*Fifteen years a safe minimum estimate of prolongation possible.*

The estimate of fifteen years as the possible prolongation of life is merely a minimum estimate. This will be seen from the following important considerations:

1. The estimate takes no account of future medical discoveries, which are now coming at such a rate that we have every reason to believe they will soon greatly increase the ratios of preventability. Cancer, for instance, has been put down with zero as its ratio of preventability, but the scientific world is intently seeking for methods of prevention and cure. Likewise "old age" has been assumed as unpreventable. Yet Metchnikoff maintains with reason that this is a malady which can be postponed.

2. The ratio of preventability of the above diseases takes little account of the cumulative influence of hygiene. Certain diseases late in life are now taken to be unpreventable or only slightly preventable on the assumption that people reach those ages in their present degree of more or less imperfect health. But on the assumption that personal hygiene had been practiced since birth, the vital resistance, which is always a deterrent of disease, would have been strengthened.

---

[a] See Dr. Edward Jarvis, "Political Economy of Health," Fifth Annual Report, Mass. Board of Health, 1874, p. 338, ff.

Professor Sedgwick tells us that evidence will be published demonstrating "Hazen's theorem," that every life saved from typhoid by better water supply means two or three persons saved from deaths from other causes. Our table shows an estimate of at least 85 per cent as the preventability of typhoid, but the coincident preventability of other diseases which this prevention of typhoid would bring about finds no place in the table. The individual estimates given for these other diseases take no account of such indirect action. Similarly, as Metchnikoff has emphasized, venereal diseases, though they seldom cause death, do shorten life, the "terminal disease" being quite different. The same is true of malaria and hook-worm disease, which predispose to tuberculosis and other terminal diseases. But in the table the ratios of preventability of tuberculosis and other diseases were constructed quite irrespective of any effect from reducing venereal diseases, malaria, and other devitalizing diseases.

In the matter of personal hygiene the cumulative influence is still more indirect, and perhaps still more powerful. It is now often remarked by insurance men that the best risks are not necessarily the best physiques, but may be the valetudinarians who practice personal hygiene.

There is a vicious circle of disease and a beneficent circle of health. The so-called "cause of death" given in death certificates is only the terminal cause. It is often merely the "last straw" of a terrible load gradually accumulated through life.

Evidently, to exploit the resources of hygiene, we need to consider a thoroughgoing change in health ideals and a consequent revolution in the conditions and habits of living. What would then happen to human longevity we can only conjecture. The possible addition to the life span might, for aught we know, be several times the fifteen years in the table.

3. The figures for the possible prolongation of life take no account of the ultimate racial effects of the new health ideals. If once a nation becomes thoroughly alive to the importance of maintaining the stamina of its citizens, this will, as we have seen, affect marriages—by putting a premium on health as one of the desiderata in a prospective husband or wife. The longevity of succeeding generations would certainly be improved—how much, it would be useless to guess.

The foregoing considerations, added to the fact that the estimates of preventability were made conservatively, will show that the addition of fifteen years is really only a first step. If clean milk will prevent infantile diarrheal diseases, if clean water will prevent deaths from typhoid and at the same time—according to Hazen's theorem—prevent two or three times as many other deaths, and if clean air will prevent tuberculosis, then it is evident that mere cleanliness in respect to these necessities will suffice to lengthen life by most if not all of the above estimate. Fifteen years is merely the "ore in sight." If we will work for it, we may get an even richer prize.

> **Within the past few years the knowledge of the causes of disease has become so far advanced that it is a matter of practical certainty that by the unstinted application of known methods of invesigation and consequent controlling action, all epidemic disease could be abolished within a period so short as fifty years.**[a]

---

[a] E. Ray Lankester, "The Kingdom of Man," New York (Holt), 1907, p. 36.

SECTION 5.—*Need of lengthening human life.*

If Metchnikoff's noble dream should be some day realized, the lengthening of human life would at once decrease the burden on the productive period. That period tends to remain 55 per cent of the total years lived, on the assumption that the working period remains 17½ to 60, but the upper limit tends to shift forward. In this way, both the absolute and relative length of the working period would be increased.

The further off the burden of old age is shifted, the easier it is for society or the individual to accumulate the wealth to provide for it. At present the burden of helpless old age is extremely serious, as those countries are beginning to realize which, like Denmark, Belgium, Germany, France, and recently England, have enacted laws to provide old-age pensions.

As life becomes more complex it requires a longer period of preparation. Preparation is education, and requires time. As the stock of knowledge increases, the period for acquiring it, or rather only enough of it to enable one to earn a livelihood, is constantly tending to increase. The age of leaving school and college is presumably growing greater.

It would be very much in keeping with the fitness of things if in this century biological science practically applied should shift the limit of the further end of the working period, the limit which we have assumed to be 60, to a later period of life. Human life would then be on a larger scale throughout. It would provide time for a longer and more thorough preparation and at the same time provide sufficient years of working life to repay this investment.

As Metchnikoff[a] well points out, one result of lengthening life will be a greater utilization of accumulated experience. We shall have less immaturity of judgment. The principle which leads to the choice for members of the judiciary of men of ripe years and knowledge will apply to every field of human activity, even those fields which are now preempted by young men because of the necessity of utilizing their vitality. It will lead to a sane and yet a vigorous conservatism. It will give to society a body of old yet hale men of experience, whose influence and worth can not be measured. As Metchnikoff has said:

> Old age, at present practically a useless burden on the community, will become a period of work valuable to the community. As the old man will no longer be subject to loss of memory or to intellectual weakness, he will be able to apply his great experience to the most complicated and the most delicate parts of the social life.[b]
>
> We may predict that when science occupies the preponderating place in human society that it ought to have, and when knowledge of hygiene is more advanced, human life will become much longer and the part of old people will become much more important than it is to-day.[c]

SECTION 6.—*The normal lifetime.*

What is the normal human lifetime?[d] Many estimates have been made, based on all sorts of reasoning, the figures extending from 75 to 200 years. Flourens's law, of doubtful value, that a mammal lives five times the length of its growing period, can not be applied generally. It is true, the horse full grown at 5 may live 25 years; sheep adult at less than 3 years may live 12; while elephants, which have an unusually tardy development, are reputed to have a lifetime of 2 centuries.

---

[a] Prolongation of Life, p. 329.

[b] Nature of Man, p. 295.

[c] Metchnikoff: "Prolongation of Life," pp. 226–227.

[d] On the topic of human longevity, see Metchnikoff: "The Prolongation of Life," Pt. II, Chaps. I, II. Shaler: "The Individual," New York (Appleton), 1901, Chap. III. Lankester: "Comparative Longevity," London, 1870, pp. 88–119.

Haller, a distinguished Swiss physiologist of the eighteenth century, thought that man ought to live to [illegible]0 years; Buffon was of the opinion that when a man did not die from some accident or disease he would reach 90 or 100 years.[a]

In man the growth period is normally continued to some time after the twentieth year; its exact limit has not been ascertained, but from the statistics gathered by the Sanitary Commission during the civil war it seems most likely that it is not usually completed until after the thirtieth year.[b]

One method which has been suggested to ascertain the natural length of life is to suppose all diseases to be completely eliminated and those who now die of them to die of old age. The median age for death from old age is 83. Metchnikoff, however, shows the error of assuming present old age to be normal. We may conclude that the normal life exceeds 83.

There must needs be, of course, a limit to the possible prolongation of life. We find in recent times few authenticated cases of persons who have lived for a hundred years. As Young, former president of the British Actuarial Society, has shown in his interesting book[c] on centenarians, most cases of supposed centenarians are either cases of conscious or unconscious exaggeration or of error in records. For instance, the Countess of Desmond is said to have lived 130 years, owing to the confusion of two persons of the same name, one of whom lived to be 100 years old, while the other, her mother, died at 30, and their lives were combined in subsequent records. There are, however, some authenticated cases. Thus, the Norwegian Drakenberg was born in 1626 and lived until 1772, aged 146. "He was married when 111 years old, and as a widower of 130 proposed to marry again, although without success."[d]

At Portland, Oreg., Mrs. Mary L. Wood died recently at the age of 120 years and under circumstances which permitted the authentication of her case by the Oregon Historical Society. From these and from other cases which might be mentioned, we may conclude that if to-day, notwithstanding all existing chances of death, it is possible for some persons to live beyond 120, the chances in the future for a larger proportion of such persons will be materially improved. Whether this proportion could ever become the major part we have as yet no means of knowing. What is needed is study, and Metchnikoff is right in believing that the study is well worth while from every point of view.

APPENDIX TO CHAPTER XI.—*Method of computing possible prolongation of life.*

SECTION 1.—*"Expectation" at median ages as short cut to average expectations.*

The table given in Chapter XI is briefly described in the chapter itself. The following additional explanations are made in regard to the statistical method employed:

---

[a] Metchnikoff, "Prolongation of Life," p. 84.

[b] Shaler, loc. cit., p. 61.

[c] T. E. Young: "Centenarians," London (C. & E. Layton), 1899.

[d] See article by Harald Westergaard, (British) Economic Journal, Vol. IX, 1899, p. 315.

The third column, giving the expectation of life which is lost or cut off by each particular cause of death, is estimated roughly by taking the expectation of life pertaining to the median age reached by those who die from the cause named. This expectation of life is taken from the Massachusetts Life Tables, 1893–1897.[a]

The method of using the median age is sufficiently exact in view of the inexact, or rather, safe, minimum estimates of preventability given in column five. A perfectly correct method would be much more laborious. Hayward's monograph on the effect on the duration of life of eliminating only one disease (tuberculosis) requires 190 pages of calculation. The true method consists in averaging arithmetically and weighting these averages according to the number dying at the various ages. Specimen computations show that the error involved by the short cut is not great.

Thus, for tuberculosis it is found that the average expectation of life lost by consumptives dying in 1906 was 32 years, whereas the expectation of life at the median age was 33 years. The former figure is a hundredfold more difficult to compute than the latter. Even the former is not strictly correct, since it applies to the deaths by ages as distributed in 1906, and not as distributed in a "stationary" population.

SECTION 2.—*Basis of estimates of preventability.*

The estimates of preventability given in column 5 need special explanation. In a few cases, these estimates are based on statistical experience.[b]

The great majority of them are based on clinical experience merely, without any exact statistics. They are thus in the nature of expert guesses. The experts in all cases are physicians. I have not entered any estimate of my own, unless item No. 36 might be so designated. This item is the residuum of deaths from unknown causes, or ill-defined causes, and is made up to a large extent of cases not properly reported in the death certificates. Inasmuch as the average preventability for all other causes in the table is over 42 per cent, it seemed safe to assign to deaths from these unknown causes a ratio of preventability of 30 per cent. But even if the preventability were entered as 0, the effect in reducing the result would be less than a year.

Those who gave to the construction of these estimates the benefit of their experience, observations, and reading were especially asked above all to be conservative. In order to avoid any possibility of exaggeration of their estimates in the table their average was taken, and then the estimate, as entered in the table, was taken either as that average or below it. In no case was the estimate entered as above the average given. When, as was true in a large proportion of cases, the different estimates agreed fairly well, the average was employed, or rather the nearest figure ending in 0, or 5 next below the average. If the individual estimates diverged widely, an estimate was used below the average, favoring the conservative estimators rather than the optimistic. Also in cases where only a few estimates were obtainable, the estimate as entered was put below the average of those given.

---

[a] S. W. Abbott, M. D.: "The vital statistics of Massachusetts for 1897, from the thirtieth annual report of the state board of health of Massachusetts." The expectation is taken as the average of the expectations for males and females.

[b] In addition to the data in regard to special diseases discussed in the text, other pertinent material has been taken into account by those who made the estimates presented in the table. For instance, from smallpox in London in 1901–2 the mortality was 34.6 per cent among the unvaccinated, 20.9 per cent among those vaccinated after the disease was apparent, and 10.3 per cent where there was protective vaccination. In Gloucester in 1895–96 the mortality among the unvaccinated was 40.8 per cent and among the vaccinated 9.8 per cent. For children under 1 year the unvaccinated had a mortality of 72 per cent, while the vaccinated were not attacked. From cerebro-spinal meningitis the average mortality was 70 per cent (Holt); the mortality under serum treatment was 25 per cent (Flexner and Jobling). For typhoid fever, Koch and his assistants stamped out the disease in Trier by isolation of the infected persons and disinfection. (Osler, The Practice of Medicine, sixth edition.) This would probably be impracticable to such an extent in a city on account of the great expense involved and the difficulty of detecting the bacillus carriers. Other figures for typhoid fever are given in the text. For diphtheria in New York City in 1889–1891 we find the mortality was 37.3 per cent, while in 1902–1904 the mortality was 10.8 per cent. The board of health began to use antitoxin in 1895. These facts were furnished by Professor Blumer. Many data on preventability are given by John C. McVail in The Prevention of Infectious Diseases, New York (Macmillan), 1907. See especially pages 16–19. Doctor Stiles, of the Public Health and Marine-Hospital Service, is soon to publish figures showing the absolute preventability of hook-worm disease, a malady prevalent in the South, but not entering into the census tables. These tables do not cover the Southern States.

In estimating the percentage of preventability for all the ninety causes of death, 18 estimators contributed. The number of estimates of preventability for each cause averaged nearly eight for each cause of death. It will be seen, therefore, that the table represents in a conservative way medical opinion as to the preventability of disease. The physicians who contributed these estimates are: Dr. Joseph M. Flint, professor of surgery, Yale Medical School; Dr. George Blumer, professor of the theory and practice of Medicine, Yale Medical School; Dr. H. L. Swain, clinical professor, Yale Medical School; Dr. Oliver T. Osborne, professor of therapeutics, Yale Medical School; Dr. J. H. Townsend, secretary of Connecticut state board of health; Dr. F. W. Wright, health officer of New Haven; Dr. Norman E. Ditman, of Columbia University; Dr. Cressy L. Wilbur, Chief of Division of Vital Statistics, Bureau of the Census; Dr. L. O. Howard, Chief of Bureau of Entomology, Department of Agriculture; Dr. William C. Woodward, chief health officer of District of Columbia; Dr. Charles V. Chapin, city health officer, Providence, R. I.; Dr. Henry B. Baker, ex-secretary Michigan state board of health, ex-president American Public Health Association; Dr. J. H. Kellogg, superintendent of the Battle Creek Sanitarium; Dr. Charles H. Castle, of Cincinnati, Ohio; Dr. Harry M. Steele, of New Haven, Conn.; Dr. L. Emmett Holt, of New York; Dr. Edwin O. Jordan, of the Memorial Institute for Infectious Diseases, Chicago, Ill.; Dr. Prince A. Morrow, president of the American Society for Sanitary and Moral Prophylaxis.

SECTION 3.—*Meaning of "preventable."*

The meaning of the word "preventable" requires some explanation.

1. It is to be noted that column 5 gives the ratio of preventability for mortality and not for morbidity. It means ratio of preventable deaths to all deaths, not to all cases of illness.

2. Since the word "preventable" implies the hypothesis of different conditions from those which actually exist, it is necessary to specify what hypothetical conditions shall be implied in the term. Doubtless tuberculosis would be over 99 per cent preventable if we should conceive as our hypothetical conditions that every individual could live on the prairies of the West, out of doors, be provided with the best of food, most congenial of tasks, and free from overwork and worry. Needless to say, the figures in the table do not imply such Utopian conditions, nor do they imply new medical discoveries. One hundred per cent of every disease might be preventable if we conceived as our hypothesis that the means of prevention are known and applied. The hypothetical condition selected for the meaning of the term "preventable" is contained in the following definition: *A "ratio of preventability" is the fraction of all deaths which would be avoided if knowledge now existing among well-informed men in the medical profession were actually applied in a reasonable way and to a reasonable extent.* The term "reasonable" is of course elastic, and will be somewhat differently interpreted by different persons, but, as in law, where "reasonable care" is often used as a proviso, it is impossible to make any more specific condition.

3. Considerable confusion exists in the minds of many people in regard to the number of deaths which might be prevented, or, as it is popularly expressed, the number of lives which might be saved. Since death is ultimately inevitable for all, no life can be saved except temporarily. It will serve to avoid confusion if "preventable" is explained as "postponable." The question arises when deaths are postponed, How long are they postponed? The answer is, They are supposed to occur according to existing rates of mortality. Thus, those saved from croup (No. 12) at age 2 will later die as do others who are living at age 2, and will therefore have the expectation of life (54 years) pertaining to that age.

4. The above explanation will serve to meet an objection which otherwise would immediately occur to the reader. If diseases of early life are prevented, the result will necessarily be an increase of the diseases in later life. For instance, if all the causes of death could be abolished except old age, there

would be a great increase in the number of deaths from old age, which, instead of constituting the 2 per cent of all deaths, which it does at present, would constitute 100 per cent.

But the fact that all lives saved will add to the later mortality is fully, and more than fully, taken into account in our calculations. When we assume that certain lives now lost at a given age might be saved, we also assume that they would not be saved again (even from the same disease), but would die off according to the old rates of mortality at successive ages. Their new lease of life would simply be the old expectation of life. As a matter of fact, lives now lost could probably be saved, not only once, but several times.

We may here explain the paradox mentioned in the text—namely, that a preventability of 42.3 per cent of deaths under present conditions does not imply that the death rate would ultimately be reduced 42.3 per cent.

The death rate would ultimately depend on conditions of the distribution of ages and diseases entirely different from those now prevailing. This will be clear if we think what would happen if the preventability expressed in the table could be immediately applied. During the ensuing year it would be found that about 42 per cent of present deaths would not occur. A consequence of this, however, would be that the persons whose lives were prolonged would die at a later period, since no death is absolutely prevented, but only postponed. Even if 100 per cent of all deaths were prevented (postponed), but the postponement were for a very short time, the effect in reducing the death rate would be extremely small. On the other hand, if only 1 per cent of the preventable deaths were postponed for a sufficiently long time, the ultimate effect would be to reduce the death rate much more than 1 per cent. After the deaths which had been postponed had reentered, a new equilibrium would be established. Under these new conditions the ratio of the deaths to the population would not be 42.3 per cent lower than at present, but only about 25 per cent. At present the average duration of life, taken from the Massachusetts table for 1893–1897, is about 45 years. The ratio of preventability in the above table would increase this life by about fifteen years, making it 60 years. The ratio of 45 to 60, showing the increase in the life span, will be the inverse of the ratio 60 to 45 in a "stationary" population, which would show the resulting reduction in the death rate. This is a reduction of 25 per cent. Thus the preventability of 42.3 per cent of deaths under present conditions and in the manner indicated in the table involves a lengthening of life of 33⅓ per cent and a reduction of the death rate, after readjustment of deaths by ages, of about 25 per cent.

SECTION 4.—*Error from abnormal age distribution of deaths in 1906.*

The table as given is constructed for deaths occurring in the calendar year 1906. Its interpretation, however, is to be made on the basis of a survivorship table. In a stationary population the age distribution of deaths in any year would be the same as in a survivorship table; but since the United States has not a stationary population, this identity holds only approximately.

The discrepancy accounts for the difference of one and three-tenths years in the prolongation of life, as calculated in the table and by means of the diagram. The latter is the more correct, as it is based on a survivorship table, or—what amounts to the same thing—on such mortality as would exist in a stationary population. The only way in which this diagram can be vitiated by the slightly abnormal age distribution of deaths in the year 1906 is as this abnormal distribution affects the average ratios of preventability used in constructing the diagram. These ratios are based on column (5) of the résumé of the table. The four figures from the table are adjusted by graphic interpolation in the usual way, so as to form a continuously varying series of figures for successive years of life. These ratios are in each case an average of the individual ratios for particular diseases, contained in the same column (5) of the larger table. The "weights" are slightly vitiated by the fact that the age distribution of deaths in 1906 is not the normal distribution of a stationary population. It is only as the "weighting" is thus affected that the diagram can be vitiated through our being forced to use the figures for 1906 instead of those for an ideal stationary population, since such figures are unobtainable. The error from this source is infinitesimal, and we may depend on the results of the diagram, 12.8 to 14.9 years, as practically free from any appreciable error due to the use of short-cut methods.

SECTION 5.—*Ratios of preventability by ages derived from ratios of diseases.*

In regard to the résumé containing the average ratios of preventability holding true during different ages, it will be observed that they are obtained indirectly, by calculating from the individual ratios of preventability for different diseases given in the table itself. Although these diseases are not absolutely limited to the times within which their median falls, there is a fairly distinct line of demarcation between the groups, especially between children's diseases and those of middle life. The table shows no disease with a median age of incidence between 8 and 23 years, and the census table of deaths for 1906 shows that a very small percentage of the total deaths occur between ages 10 and 20. Even if the diseases considered for the four epochs of life given in the résumé did extend somewhat into the regions of the adjacent epochs, the effect would not change the result appreciably and would be as likely to change it in one direction as the other. The reason is that the items of the column in the résumé for "ratio of preventability" are obtained by dividing the figures in column 6 by those in column 4, each of these two being found by adding the individual figures in the table for each age group concerned. The extension of diseases of an age group outside of that group will apply equally to both terms of the ratio, those in the fourth and sixth columns, and will not substantially affect the quotient in the fifth column.

SECTION 6.—*Allowance for weakness of prolonged lives.*

The use in column 2 of the expectations of life derived from the Massachusetts 1893–1897 life table is equivalent to the assumption that if preventable deaths were prevented the lives thus saved would proceed to die off according to the mortality of Massachusetts, 1893–1897. This assumes that since 1893–1897 there has been no improvement in the expectation of life, and that the saved lives will not share in the improvement which the table itself shows forth. The reason that a later life table than for 1893–1897 was not used is that no later life table is available. If it were, it would show larger figures in column 2, and consequently a larger total result for the possible prolongation of life than fourteen years.

The reason the "expectation" in column 3 does not take account of the effect of the improvement in mortality resulting from the table is that this improvement can not be calculated until column 3 is filled, and we prefer to use as a first approximation a conservative figure in column 3, rather than to guess at more likely figures. The conservative assumption used seems also advisable, because of the fact that in the 42.3 per cent of persons in the life table who would be saved from death and given a new lease of life there would be suffered a greater mortality than that of the average persons that now pass that age in safety, for—on the principle of the survival of the fittest—it is intrinsically probable that those who now die at any age are weaker than those who do not.

How much allowance should be made for this factor of differential mortality it is impossible to say with certainty. But in another paper [a] I have dealt with the same question applied to tuberculosis. Taking the figures of Dr. Lawrason Brown, giving the mortality experience among the apparently cured cases of tuberculosis discharged from the Adirondack Cottage Sanitarium, and making certain allowances, it seems that if tuberculosis were prevented its present victims would have more than three-fourths of the expectation of life belonging to others. Let us assume that this ratio is equally conservative as applied to all other cases of prolongable life. Now, it so happens that the expectation of life at birth in the Massachusetts life table of 1893–1897 is almost exactly three-fourths of the expectation which our table and diagram shows would be possible if prevention were properly practiced. This would give 45 years as the expectation of life at birth for the saved lives, 61 for other lives, and 59 for all lives. Surely this seems sufficient allowance for the existence of any possible inferiority among the lives which would be saved.

SECTION 7.—*Diagram "Possible I," making this allowance, compared with "Possible II," omitting it.*

If no allowance for inferiority among saved lives were necessary, the results of the calculation given in the table would be only a first approximation and would need to be followed by successive and closer approximations. We can get much quicker results by means of the diagram and a planimeter.

---

[a] "The cost of tuberculosis in the United States and its reduction," read before the International Congress on Tuberculosis, 1908.

If we apply the ratios of preventability for these four groups, we are able to construct the new survivorship table on the basis of Mr. Abbott's for 1893–1897. All that is necessary is to begin the new survivorship table at the same point that the old begins, and continue from that point and every other point throughout its course by the following procedure: Through the point draw a line downward and to the right for one year, at the same percentage slope as Abbott's table shows for that year. This line indicates what survivors there would be if their mortality were not affected at all by the ratio of preventability. The deaths during that year would be represented by the drop of the curve within the year. Next, taking the proper fraction of this drop, as indicated by the ratio of preventability, we pass vertically upward this amount from the end of the line, and from the new point so obtained proceed in like manner for each subsequent year. The result is a series of teeth the upper points of which are points on the required curve. Joining these points, we obtain the curve. This process explains the theory. This gives the table called "Possible I," and takes full account of the fact that the ratios of preventability continue to apply to saved life as much as to other life. The table "Possible I" represents the survivorship table, under the assumption that the lives saved once are given no further advantages, but follow thereafter the old law of mortality, that for 1893–1897.

SECTION 8.—*Reciprocal relation between longevity and mortality shown by diagram.*

We may take this opportunity to explain, for the benefit of the general reader, the reciprocal relations existing between the death rate in a stationary population and the average duration of life. Consider the diagram "Massachusetts, 1893–1897." It shows the life history of 100,000 persons born. Let us suppose a community unaffected by emigration or immigration, and in which there are 100,000 births each year. Let us suppose, further, that the 100,000 persons born each year die afterwards according to the law of mortality represented by the curve "Massachusetts, 1893–1897." Evidently in such a community there will not only be 100,000 births, but there will be 100,000 deaths each year, and the population will be stationary. It will also be true that the same diagram can be taken to represent the age distribution of this stationary population. Thus, those living at age 10 will be the survivors of the 100,000 born ten years ago, and the number of such survivors is the ordinate of the curve at 10 years. Thus, every ordinate of the curve represents not only the survivors to a certain age out of 100,000 births, but also represents the number in the population at that age. The area of the curve therefore represents total population (when regarded as made up of vertical sections). It likewise represents the total number of years lived by 100,000 persons (when regarded as made up of horizontal sections). Now, the death rate is the ratio of deaths to population—i. e., the ratio of 100,000 to the area of the curve. The average duration of life is the total years lived by 100,000 persons divided by 100,000—that is, it is the area of the curve divided by 100,000. These are clearly reciprocals.

CHAPTER XII.—*The money value of increased vitality.*

SECTION 1.—*Money appraisal of preventable wastes.*

Estimates of the money value of preventable wastes depend on the valuation of *human life*, of which several appraisals have been attempted.

Prof. J. S. Nicholson estimated that in Great Britain human labor capitalized was worth five times all other capital.[a]

Engel computed that each child costs 100 marks at birth, 110 marks the first year, 120 the second, and so on. At 20 he will have cost 2,310 marks, or $560. But one-half die before 20. Hence each person who reaches the age of 20 actually costs society much more than $560; possibly as high as $1,000, if Engel's estimates are correct. Professor Mayo-Smith estimated that men and women between the ages of 15 and 45 averaged $1,000 in value.[a] As to the value of immigrants to this country, he says: "Every immigrant must represent labor value with at least the value of a slave. It is figured that each immigrant is worth $875."[b]

---

[a] See "The Living Capital of the United Kingdom" (British) Economic Journal, 1891.

The best method of estimating the economic value of life and its increased duration is by the capitalization of earning power. Dr. William Farr, of England, has estimated that a baby born to an English agricultural laborer is worth in capitalized earning power about £5, or $25. This is the discounted value of its future earnings estimated on its probable life less the discounted value of the cost of rearing it during the period of dependence and of maintaining it when helpless through old age. In the same way he estimates the value of a life at other ages—10 years, 20 years, 50 years, etc.[c]

In lieu of any estimates for the United States we may take Farr's figures for agricultural laborers as representing, roughly, the relative worth of a man or woman in the United States. To obtain the absolute figures, therefore, we need simply to multiply these of Farr by a constant factor representing the ratio between the average earnings in the United States and the earnings which Farr uses as the yearly income of an agricultural laborer.

We take, in the absence of any good statistics, $700 per annum as a guess, but a safe minimum[d] for the average earnings of workers of all grades, from day laborers to railroad presidents. This assumes that all of the working years are actually employed in work. But since about one-fourth of the persons of working age are not workers, but are supported (for the most part) by earnings of capital, the average should be cut down to three-fourths of this figure, or $525.

Substituting this figure for the £31 in Farr's table, we can reconstruct it to represent the minimum worth of the average American life at different ages. The following figures are taken from the table thus computed:

Age.	Net worth of a person, in dollars.	Age.	Net worth of a person, in dollars.
0	90	30	4,100
5	950	50	2,900
10	2,000	80	−700
20	4,000		

From the table from which these figures are taken it is possible to base minimum estimates for (1) the average economic value of the inhabitants of the United States by using the census figures for age distribution of population; this calculated average is $2,900; (2) the average economic value of the lives now sacrificed by preventable deaths, using the age distribution of deaths, and the percentages of preventability; this calculated average is $1,700.

---

[a] Mayo-Smith, Statistics and Sociology, p. 177.

[b] Mayo-Smith, Emigration and Immigration.

[c] See Farr, "Vital Statistics," p. 536.

[d] See Fisher "Cost of tuberculosis," read before the International Congress on Tuberculosis, Washington, 1908. This is the estimated minimum used in my paper on the "Cost of tuberculosis." The calculations are based on $1 a day as the ordinary minimum earnings of unskilled labor, and assume a distribution of a number of earners of high amounts according to the scale of distribution which Professor Pareto finds fairly uniform in form, although not in amount in various countries. The late honorable Carroll D. Wright, whose opinion is worth more, probably, than that of any other man in the United States, stated that he would not regard $1,000 as excessive. The figure is intended to include the earnings of women (including housewives as earners).

The first figure shows that what might be called the vital assets of the United States for the population of over 85,500,000, as estimated by the census of 1907, amount in value to 85,500,000×$2,900, or $250,000,000,000, which, though a minimum estimate, greatly exceeds the value of all other wealth;[a] the second figure enables us to estimate the needless waste of our vital assets.

If we take the estimate of Professor Willcox of the death rate in the United States, as at least 18 per 1,000 for the 85,500,000 persons estimated by the census as the population of the United States in 1907, we have 1,500,000 as the number of deaths in the United States per annum. Of these 1,500,000 deaths, 42 per cent, or 630,000, are annually preventable or postponable. Since each postponement would save on the average $1,700, the national annual unnecessary loss of capitalized net earnings is 630,000×$1,700, or $1,070,000,000, or about $1,000,000,000.

We saw in Chapter III that, with our present population, there are always about 3,000,000 persons in the United States on the sick list. For the most part these persons are older than the average. Farr gives a table[b] showing that morbidity increases with age in geometric progression. By means of his table we may calculate on the same basis as the previous calculations—that of the 3,000,000 sick, very close to a third, or 1,000,000 persons, are in the working period of life. Assuming that average earnings in the working period are $700, and that only three-fourths of the one million potential workers would be occupied, we find over $500,000,000 as the minimum loss of earnings.

The cost of medical attendance, medicine, nursing, etc., is conjectured by Doctor Biggs in New York to average for the consumptive poor at least $1.50 per day of illness. The cost per day of other illnesses than tuberculosis is presumably greater, and also the cost per day for other classes is higher than for the poor. Applying this to the 3,000,000 years of illness annually experienced, we should have $1,500,000,000 in all as the minimum annual cost of this kind.

The statistics of the Commissioner of Labor[c] show that the average expenditure for illness and death amount to $27 per annum. This is for workingmen's families only. But even this figure, if applied to the 17,000,000 families of the United States, would make the total bill for caring for illness and death $460,000,000. The true cost may well be more than twice this sum. Certainly this estimate is more than safe and is only one-third of the sum obtained by using Doctor Biggs's estimate.

The sum of the costs of illness, including loss of wages and cost of care, is thus $460,000,000+$500,000,000, or $960,000,000.

The above estimate is a general one for all illness. It would be possible to offer figures for the particular losses from particular diseases. Thus, from tuberculosis, the gross loss of earnings by illness and of potential earnings cut off by death, together with the expenses of illness, etc., amount to over $1,000,000,000 per annum.[a]

---

[a] Mr. Le Grand Powers, of the Bureau of the Census, Washington, estimates that the total wealth in America (exclusive of human beings) amounts to $107,000,000,000.

[b] Vital Statistics, p. 510.

[c] Eighteenth Annual Report, 1903, p. 509.

Of the sum mentioned, the loss to the consumptives themselves amounts to over $660,000,000, leaving $440,000,000 as the loss to other members of the community. At least three-fourths of these costs are preventable. Dr. George M. Kober thinks it is conservative to say that the annual cost of typhoid in the United States is $350,000,000[b] and Dr. L. O. Howard believes that malaria alone costs the country $100,000,000 annually, and the insect diseases generally $200,000,000.[c] He points out that one great item of loss is the reduced value of real estate in malarial regions. By drainage and destruction of mosquitoes most of this waste could be saved. The cost of the care of the insane and feeble-minded is estimated by Charles L. Dana at $85,000,000 annually.[d] What fraction of these costs is preventable it is difficult to say. The economic loss due to alcohol has been variously estimated.[e] Of the billion dollars or more found to represent the cost of illness, by far the major part is certainly avoidable. This is the belief of the best observers, such as Doctor Gulick, Doctor Kellogg, Mrs. Richards, Doctor Anderson, and others. Unfortunately there are no exact statistics of preventability. We feel safe, however, in concluding that at least half a billion could be saved from the present cost of illness. This, added to the loss by preventable deaths of potential earnings of a billion, gives at least a billion and a half of preventable waste. This does not include the losses from inefficient work due to drunkenness or other vicious habits; nor does it include the cost of "undue fatigue," which we have some reason to believe exceeds in its effect on efficiency the loss from illness. But it would not be possible to state this loss in any definite or convincing figures.

The actual economic saving annually possible in this country by preventing needless deaths, needless illness (serious and minor), and needless fatigue, is certainly far greater than one and a half billions, and may be three or more times as great.

Dr. George M. Gould estimated that sickness and death in the United States cost $3,000,000,000 annually, of which at least a third is regarded as preventable.[f]

> The trouble is the public does not believe in this waste from being "just poorly," and "so as to be about." It has no conception of the difference between working with a clear brain and steady hand and with a dull and nerveless tool. They must be convinced somehow.[g]

SECTION 2.—*The cost of conservation.*

It costs no more to "raise" a man capable of living for 80 years than it does to "grow" one who has not the capacity of living to be 40 years old.[a]

We have seen how much potential value of life is now allowed to be wasted which could be prevented. But the question remains, What would it cost to conserve it? It is, of course, not possible to answer this question definitely and fully. The best we can do is to point out specific instances of the health returns which follow on investments in the improvement of vital conditions.

The following examples will show the returns which may be expected from well-planned expenditures on behalf of public health:

> The city of Pittsburg is just installing a great municipal filter plant for the purification of its principal water supply, at an expense of upward of $7,000,000. It is reasonable to estimate that in a year or two this should effect a saving of 100 deaths a year from typhoid fever, for the number of typhoid-fever deaths of late years has been 400 or more yearly. Valuing these lives at $5,000 each, as is customary, the saving effected by the purification works should be half a million dollars' worth of human life annually, making the building of the filter a sound and profitable economic as well as humanitarian measure. But if, as Mr. MacNutt and I have shown, Hazen's theorem is true, then for every 100 deaths saved from typhoid fever at least 200 will be saved from other causes, which means at least $1,000,000 more saved to the city of Pittsburg annually of its present waste of human life.[b]
>
> England reckons that the lives saved through the lowered death rate, from what it was between 1866 and 1875 to what it became in the period reaching from 1880 to 1889, amounted to 858,804. This represents on the English basis of the per capita valuation of each life ($770) a social capital of $650,000,000 saved. In ten years England has more than regained the sum spent in fifteen years for sanitary improvements, though the average annual expenditure has been $42,000,000.[c]
>
> The achievement of Huddersfield, England, is especially noteworthy. The average number of deaths of infants for ten years had been 310. By a systematic education of mothers the number was in 1907 reduced to 212. The cost of saving these 98 lives was about $2,000.[d]

A saving of infant life is recorded by Doctor Chapin in Providence:

> We attempted for two years to distribute clean milk to the babies of the poor, but this year we decided that the money could better be spent on trained nurses. Thus far we have expended about $900 for this purpose. Two hundred and thirty-five sick children, of whom very many were very sick, have been cared for. Of these only 20 have died. From a study of our statistics I should judge that the reduction in infant mortality effected by the nurses was at least 25 deaths, and it may be that as many as 40 lives were saved.[e]

At the funeral of Maj. Walter Reed, the man who did so much to prove the correctness of Doctor Finley's discovery that the mosquito is the carrying agent for the yellow-fever germ, Gen. Leonard Wood declared that this discovery is saving more lives annually than were lost in the Cuban war, and that it is saving the commercial interests of the world a greater financial loss each year than the cost of the entire Cuban war.[a]

[b] W. T. Sedgwick: "The call to public health," Science, 1908, p. 198.

Since the foregoing was written, there has appeared in "Charities," February 6, 1909, "Thirty Five Years of Typhoid" by Frank E. Wing, in which it is shown that there were in 1907, in Pittsburg, 4,921 cases of typhoid, of which 622 died; and that the cost per patient, irrespective of the lives lost, was $128, making the cost for the city $694,000. Reckoning $4,000 as the value of each life lost, the total annual money cost from typhoid in Pittsburg is over $3,000,000, and, according to Hazen's theorem, already mentioned, this is probably not one-half nor even one-third of the total.

[e] Ibid.

As to what the stamping out of yellow fever means, in money terms, the following is significant:

> It has been estimated that the yellow fever epidemic of 1878 invaded 132 towns, caused a mortality of 15,954 persons, and that the pecuniary loss to the country was not less than $100,000,000 in gold.[b]

The economic loss to Philadelphia, caused by the smallpox epidemic of 1871–72 has been estimated by Doctor Lee at $22,000,000. This includes loss to travel and traffic on railroads, loss to hotel keepers, merchants, and manufacturers, cost of care of sick, loss of time, and the expense of burial. A vaccine bureau with physicians, a disinfecting station, and the inauguration of a campaign of education capable of forestalling the whole epidemic would have cost $700,000.[c]

It is reported that San Francisco plans an investment of $30,000,000 in stone and concrete quays to prevent rodents from infecting the city, and this is regarded by experts as worth while many times over.

In respect to hook-worm disease, rating the earning per diem of the southern farm laborer at 75 cents, 28 observers report that average laborers infected with hook-worms earn 40 cents per diem. Ten observers having cotton-mill practice report unanimously that the disease is very prevalent among cotton-mill laborers, and rating the average mill laborers at $1.50 per diem, they consider 75 cents as a fair rating for hook-worm bearing laborers.[d]

> It would be difficult to even roughly estimate the cost of this disease to the South, but from what we know of it in this State I would say that it costs South Carolina not less than $30,000,000 per year, and this inability to perform regular and efficient labor is the smallest part of the cost.[e]

It has been figured that the hook-worm disease of the South could be wiped out within a generation[f] through the expenditure of from one to two millions of dollars by federal and state agencies. It costs about 15 to 75 cents (wholesale) for drugs to cure a case of hook worms. In three months the quantity of red corpuscles in the blood can easily be increased 10 to 50 per cent, according to the severity of the case, and the[g] absenteeism of the victims could easily be reduced 25 per cent.

> Another noteworthy result of well-directed sanitary effort is the reduction of hook-worm disease in Porto Rico. As you are doubtless aware, this disease causes a tremendous lowering of the physical efficiency of the people of that island. As you may see by the report of the special commission for 1906 and 1907 made to Governor Post, 89,000 people were treated, and for the most part cured, for 54 cents each.[h]

Medical inspection in our schools also returns large dividends on small investments.

> Using these data as a basis, we have the annual expenditure for medical inspection of $345,135 in those cities from which we have succeeded in obtaining data. It seems probable, although this is frankly a guess, that the total annual expenditure for medical inspection of schools in the United States at the present time is perhaps $500,000.[a]
>
> The money saved by enabling thousands of children to do one year's work in one year, instead of in two or three years, would greatly exceed the total expense of examining all school children in all boroughs.[b]

Doctor Jessen has shown that the cost of a school dental clinic in Germany is only one mark per year per child.[c] The cost saved must be very many times this sum. Dr. Herbert L. Wheeler, of New York, estimates that the Children's Aid Dental Clinic in New York cost $342 for the last fiscal year (35 cents per operation and 70 cents per child treated). He reckons that the neglect of these slight repairs would later have cost far more in dentistry, as well as over $2,000 worth of lost time. These losses are of course of minor importance compared with the pain, inconvenience, and secondary effects on health and efficiency which are inevitably associated with bad teeth.

Mr. Edwin Chadwick, who was once secretary of the English National Board of Health, stated that a sanitary "engineer ought to contract for the reduction of the sickness and death rate, in such a city as Glasgow, by at least one-third, for a penny a head of the entire population."[d]

> It is necessary, if we are to do our utmost, to spend a thousand pounds of public money on this task where we now spend one pound. It would be reasonable and wise to expend ten million pounds a year of our revenues on the investigation and attempt to destroy disease. Actually what is so spent is a mere nothing, a few thousands a year. Meanwhile our people are dying by thousands of preventable disease.[e]

Mr. Hiram J. Messenger, actuary of the Travelers Insurance Company, of Hartford, has constructed and sent me a table showing that life insurance companies could probably make money now by taking a hand in the public-health movement, with the purely commercial object of reducing their death losses. He says:

> This table shows that if the companies were to expend $200,000 a year for this purpose and as a result should decrease their losses by the almost insignificant amount of twelve one-hundredths of 1 per cent, they would save enough to cover the expense. If such a plan as this were placed on a purely scientific basis and carried out by good business methods and all the companies pulled together for the common good, I should expect a decrease in death claims of more than 1 per cent. And a decrease in death claims of 1 per cent would mean that the companies would save more than eight times as much as they expended or would make a net saving of more than seven times the expense—which would be about a million and a half dollars a year.

The examples given show tangible returns on the investment of several thousand per cent as a rule. While it would be impossible to state in general terms how rich a return lies ready for public or private investments in good health, the foregoing examples and numerous others show that the rate of this return is quite beyond the dreams of avarice. Were it possible for the public to realize this fact, motives both of economy and of humanity would dictate immediate and generous expenditure of public moneys for improving the air we breathe, the water we drink, and the food we eat, as well as for eliminating the dangers to life and limb which now surround us.

CHAPTER XIII.—*The general value of increased vitality.*

SECTION 1.—*Disease, poverty, and crime.*

In the preceding chapter we have attempted to estimate in money the preventable wastes from disease and death. Although the figures for national losses strike the popular imagination, they have little significance; in fact, money estimates in this field, even when made on the per capita basis, are of little value except as emphasizing the overwhelming importance of human vitality compared with those interests which are usually measured in money. It is impossible in any true sense to measure human life in terms of dollars and cents.[a] The measure of life may perhaps be found in happiness, or the satisfactions enjoyed between birth and death, less the dissatisfactions. Is life worth living? has been a much asked question, especially since Mr. Mallock wrote a book with that title. The witticism sometimes given in answer, "That depends upon the liver," is true in both of its two meanings. A life of happiness is always worth living, and a life of usefulness, which brings happiness to others, is doubly worth living.

It is hardly necessary to recount all the conditions which tend to produce happiness. No one would question that the most fundamental condition of all is health, in spite of exceptional cases in which unhealthy people are found happy, and healthy people unhappy. It would be impossible to express in exact terms the extent to which improved health could increase human happiness; but every observer of human misery among the poor reports that disease plays the leading rôle. Students of criminology and vice agree that these are chiefly the result of morbid conditions and habits. Health reform brings in its train great and lasting reductions in poverty, criminality, and vice.

We began this report by showing the relation between the conservation of health and the conservation of wealth. The broadest view of this relation is, as Emerson has said, that "Health is the first wealth," and as such it is treated by many economists.[b]

---

[a] Even as a measure of what economists call "utility," a money estimate is misleading, for the reason that the "marginal utility" of money varies with different persons. For instance, a week's wages of $10 lost to a poor wage-earner is in such an estimate counted on a par with an expenditure of $10 by a wealthy invalid for a dainty morsel of food, although the loss in "utility" to the former is vastly greater than that to the latter.

[b] Among those who have included health in the category of wealth are Davenant, Petty, Canard, Say, McCullough, Roscher, Wittstein, Walras, Engel, Weiss, Dargun, Ofner, Nicholson, and Pareto. See Irving Fisher: "The Nature of Capital and Income," New York (Macmillan), 1906, p. 5.

Without enlarging or insisting upon this concept, it is obvious that by the conservation of health we may ultimately save billions of dollars of wasted values, and that this conservation is intimately related to conservation of all other kinds.[a]

We have already seen the vicious circle set up between poverty and disease, each of which tends to produce the other. Metchnikoff[b] contends that health and morality are correlative, if not interchangeable, terms. A similar idea has been elaborated statistically by Dr. George M. Gould.[c] The subject is worth much further study. National efficiency is crippled by any one or all of the parts of the vicious circle—disease, poverty, vice, vagabondage, crime. It would be interesting to study the tramp problem, which represents an enormous waste of labor power, in relation to all these phenomena.

SECTION 2.—*Conservation of natural resources.*

It is also true that health begets wealth, and vice versa. Whatever diminishes poverty or increases the physical means of welfare has the improvement of health as one of its first and most evident effects. Therefore an important method of maintaining vital efficiency is to conserve our natural resources—our land, our raw materials, our forests, and our water. Only in this way can we obtain food, clothing, shelter, and the other means of maintaining life. Conversely, the conservation of health will tend in several ways to the conservation of wealth. First of all, the more vigorous and long-lived the race, the better utilization can it make of its natural resources. The labor power of such a race is greater, more intense, more intelligent, and more inventive.

The development of our natural resources in the future will be more dependent on technical invention[d] than upon the mere abundance of materials.

Just as in warfare it is not so much the gun as the man behind the gun that makes for success, so in industry, as Doctor Shadwell[e] has shown, skill, knowledge, and inventiveness are the chief factors in determining commercial success and supremacy. The backward nations, like China, are characterized by lack of modern inventions. The nations which are industrially most advanced have the railway, the steamship, the power loom, metal working, and innumerable arts and crafts. The change of Japan from a backward to a forward nation is at bottom the introduction of inventions. If conservation prevents lessened fertility, invention makes two blades of grass grow where one grew before.

Future industrial competition will be increasingly a contest of invention. The world rivalry to develop the best system of wireless telegraphy or the best airships is but one example. The future will see the greatest strides taken by the nation which is the most inventive. Now, the primary condition of invention is vitality, a clear brain in a normal body. It is no accident that Edison is a health culturist, or that Krupp, Westinghouse, and other pioneers in industrial development have been men of vigor of mind and body.

[d] Since the above was written, President Charles S. Howe, of Cleveland, has presented this point in detail. See "The function of the engineer in the conservation of the natural resources of the country," Science, Oct. 23, 1908.

[e] Arthur Shadwell in his admirable "Industrial Efficiency" (2 vols.). London (Longmans), 1906.

Finally, the conservation of health will promote the conservation of other resources by keeping and strengthening the faculty of foresight. One cause of poverty in the individual and the nation is lack of forethought.[a]

One of the first symptoms of racial degeneracy is decay of foresight. Normal, healthy men care for and provide for their descendants. A normal, healthy race of men, and such alone, will enact the laws or develop the public sentiment needed to conserve natural resources for generations yet unborn. When in Rome foresight was lost, care for future generations practically ceased. Physical degeneracy brought with it moral and intellectual degeneracy. Instead of conserving their resources the spendthrift Romans, from the emperor down, began to feed on their colonies and to eat up their capital. Instead of building new structures they used their old coliseum as a quarry and a metal mine.[b]

The problem of the conservation of our natural resources is therefore not a series of independent problems, but a coherent all-embracing whole. If our nation cares to make any provision for its grandchildren and its grandchildren's grandchildren, this provision must include conservation in all its branches—but above all, the conservation of the racial stock itself.

CHAPTER XIV.—*Things which need to be done.*

SECTION 1.—*Enumeration of principal measures.*

In order that American vitality may reach its maximum development, many things need to be done. Among them are the following:

1. The National Government, the States, and the municipalities should steadfastly devote their energies and resources to the protection of the people from disease. Such protection is quite as properly a governmental function as is protection from foreign invasion, from criminals, or from fire. It is both bad policy and bad economy to leave this work mainly to the weak and spasmodic efforts of charity, or to the philanthropy of physicians.

2. The National Government should exercise at least three public health functions: First, investigation; second, the dissemination of information; third, administration.

It should remove the reproach that more pains are now taken to protect the health of farm cattle than of human beings. It should provide more and greater laboratories for research in preventive medicine and public hygiene. Provision should also be made for better and more universal vital statistics, without which it is impossible to know the exact conditions in an epidemic, or, in general, the sanitary or insanitary conditions in any part of the country.

---

[a] See Irving Fisher: "The Rate of Interest," New York (Macmillan), 1907.

[b] See John Rae: "Sociological Theory of Capital," edited by Prof. C. W. Mixter, New York (Macmillan), 1905.

It should aim, as should state and municipal legislation, to procure adequate registration of births, statistics of which are at present lacking throughout the United States.

The National Government should prevent transportation of disease from State to State in the same way as it now provides for foreign quarantine and the protection of the nation from the importation of disease by foreign immigrants. It should provide for the protection of the passenger in interstate railway travel from infection by his fellow-passengers and from insanitary conditions in sleeping cars, etc.

It should enact suitable legislation providing against pollution of interstate streams.

It should provide for the dissemination of information in regard to the prevention of tuberculosis and other diseases, the dangers of impure air, impure foods, impure milk, imperfect sanitation, ventilation, etc. Just as now the Department of Agriculture supplies specific information to the farmer in respect to raising crops or live stock, so should one of the departments, devoted principally to health and education, be able to provide every health officer, school-teacher, employer, physician, and private family with specific information in regard to public, domestic, and personal hygiene.

It should provide for making the national capital into a model sanitary city, free from insanitary tenements and workshops, air pollution, water pollution, food pollution, etc., with a rate of death and a rate of illness among infants and among the population generally so low and so free from epidemics of typhoid or other diseases as will arouse the attention of the entire country and the world.

There should be a constant adaptation of the pure-food laws to changing conditions. Meat inspection and other inspection should be so arranged as to protect not only foreigners, but our own citizens. The existing health agencies of the Government should be concentrated in one department, better coordinated, and given more powers and appropriations.

3. State boards of health and state legislation should provide for the regulation of labor of women, should make physiological conditions for women's work and prevent their employment before and after childbirth; should regulate the age at which children shall be employed, make reasonable regulations in regard to hours of labor and against the dangers in hazardous trades, and especially against the particular dangers of dust and poisonous chemicals; should make regulations for sanitation and provide inspection of factories, schools, asylums, prisons, and other public institutions. Where municipalities have not the powers to enact the legislation above mentioned with reference to local conditions, the necessary legislation or authority should be provided by the State. Or where by reason of the small size of the town no efficient local action is possible, the State should exercise the necessary functions. It should in such cases advise and supervise local boards of health. It should have an engineering department and advise regarding the construction of sewers and water supplies. Pollution of such supplies, unless entirely local, should be prevented by the State, which should be equipped with laboratories for the analysis of water, milk, and other foods. Suitable legislation should be passed regulating the sale of drugs, especially preparations

containing cocaine, opium, or alcohol. Legislation—not too far in advance of public sentiment needed to enforce it—should be passed regulating the sale of alcoholic beverages. State registration of births, deaths, and cases of illness should be much more general and efficient than at present.

4. Municipal boards of health need to have more powers and greater appropriations; less political interference and better trained health officers; more support in public opinion. Their ordinances in regard to expectoration, notification of infectious disease, etc., should be better enforced by the police departments.

More legislation should be advocated, passed, and enforced to the end that streets may be kept clean, garbage properly removed, sewage properly disposed of, air pollution of all kinds prevented, whether by smoke, street dust, noxious gases, or any other source. Noises also should be lessened.

Municipalities need also to take measures to prevent infection being carried by flies, mosquitoes, other insects and vermin, and by prostitution. They need to guard with greater care the water supply, and in many cases to filter it; they should make standards for milk purity and enforce them; they should also regularly inspect other foods exposed for sale; provide for sanitary inspection of local slaughterhouses, dairies, shops, lodging and boarding houses, and other establishments within the power of the particular municipality; they should make and enforce stricter building laws, especially as relating to tenements, to the end that dark-room tenements may be eliminated and all tenements be provided with certain minimum standard requirements as to light, air, and sanitary arrangements.

5. School children should be medically inspected and school hygiene universally practiced. This involves better protection against school epidemics, better ventilation, light, and cleanliness of the schoolroom, the discovery and correction of adenoids, eye strain, and nervous strain generally, and the provision for playgrounds. Sound scientific hygiene should be taught in all schools, public, private, normal, and technical, as also in colleges and universities.

6. The curricula of medical schools should be rearranged with a greater emphasis on prevention and on the training of health officers. Sanatoria and hospitals, dispensaries, district nursing, tuberculosis classes, and other semipublic institutions should be increased in number and improved in quality. The medical profession, keeping pace with these changes, should be the chief means of conveying their benefits to the public. Universities and research institutions need to take up the study of hygiene in all its branches. Now that the diseases of childhood are receiving attention, the next step should be to study the diseases of middle life. These are diseases, to a large extent, of nutrition and circulation, and consequently these subjects should receive special attention. Intelligent action must rest on knowledge, and knowledge of preventing disease is as yet extremely imperfect.

7. In industrial and commercial establishments employers may greatly aid the health movement, and in many cases make their philanthropy self-supporting by providing social secretaries, lunch and rest rooms, physiological (generally shorter) hours of work, provision for innocent amusements, seats for women, etc.

Life insurance companies could properly and with much profit club together to instruct their risks in self-care and secure general legislation and enforcement of legislation in behalf of public health.

8. The present striking change in personal habits of living should be carried out to its logical conclusion until the health ideals and the ideals of athletic training shall become universal. This change involves a quiet revolution in habits of living, a more intelligent utilization of one's environment, especially in regard to the condition of the air in our houses, the character of the clothes we wear, of the site and architecture of the dwelling with respect to sunlight, soil, ventilation, and sanitation, the character of food, its cooking, the use of alcohol, tobacco, and drugs, and last, but not least, sex hygiene in all its bearings.

9. The fight against disease will aid in the fight against pauperism and crime. It is also true that any measures which tend to eliminate poverty, vice, and crime will tend to improve sanitary conditions.

10. Finally, eugenics, or hygiene for future generations, should be studied and gradually put in practice. This involves the prohibition of flagrant cases of marriages of the unfit, such as syphilitics, the insane, feeble-minded, epileptics, paupers, or criminals, etc. The example of Indiana in this regard should be considered and followed by other States, as also in regard to the unsexing of rapists, criminals, idiots, and degenerates generally. A public opinion should be aroused which will not only encourage healthy and discountenance degenerate marriages, but will become so embedded in the minds of the rising generation as will unconsciously, but powerfully, affect their marriage choices.

ECONOMIC LOSS TO THE PEOPLE THROUGH INSECTS THAT CARRY DISEASE.

By L. O. Howard, Ph. D.,
Chief Bureau of Entomology, United States Department of Agriculture.

It has been definitely proven and is now generally accepted that malaria in its different forms is disseminated among individuals of the human species by mosquitoes of the genus *Anopheles*, and that the malarial organism gains entrance to the human system, so far as known, only by the bite of mosquitoes of this genus. It has been proven with equal definiteness, and has also become generally accepted, that yellow fever is disseminated by the bite of a mosquito known as *Stegomyia calopus* (possibly by the bites of other mosquitoes of the same genus), and so far as has been discovered this disease is disseminated only in this way. Further, it has been scientifically demonstrated that the common house fly is an active agent in the dissemination of typhoid fever, Asiatic cholera, and other intestinal diseases by carrying the causative organisms of these diseases from the excreta of patients to the food supply of healthy individuals; and that certain species of fleas are the active agents in the conveyance of bubonic plague. Moreover, the tropical disease known as "filariasis" is transmitted by a species of mosquito. Furthermore, it is known that the so-called "spotted fever" of the northern Rocky Mountain regions is carried by a species of tick; and it has been demonstrated that certain blood diseases may be carried by several species of biting insects. The purulent ophthalmia of the Nile Basin is carried by the house fly. A similar disease in the Fiji Islands is conveyed by the same insect. Pink eye in the southern United States is carried by minute flies of the genus *Hippelates*. The house fly has been shown to be a minor factor in the spread of tuberculosis. The bedbug has been connected with the dissemination of several diseases. Certain biting flies carry the sleeping sickness of Africa. A number of dangerous diseases of domestic animals are conveyed by insects. The literature of the whole subject has grown enormously during the past few years, and the economic loss to the human species through these insects is tremendous. At the same time this loss is entirely unnecessary; the diseases in question can be controlled, and the suppression of the conveying insects, so absolutely vital with certain of these diseases and so important in the others, can be brought about.

MOSQUITOES.

Aside from the loss occasioned by these insects as carriers of specific diseases, their abundance brings about a great monetary loss in other ways.

Possibly the greatest of these losses is in the reduced value of real estate in mosquito-infested regions, since these insects render absolutely uninhabitable large areas of land available for suburban homes, for summer resorts, for manufacturing purposes, and for agricultural pursuits. The money loss becomes most apparent in the vicinity of large centers of population. The mosquito-breeding regions in the vicinity of New York City, for example, have prevented the growth of paying industries of various kinds and have hindered the proper development of large regions to an amount which it is difficult to estimate in dollars and cents, and which is almost inconceivable. The same may be said for other large cities near the seacoast, and even of those inland in low-lying regions. The development of the whole State of New Jersey has been held back by the mosquito plague.

Agricultural regions have suffered from this cause. In portions of the Northwestern States it has been necessary to cover work horses in the field with sheets during the day. In the Gulf region of Texas at times the market value of live stock is greatly reduced by the abundance of insects. In portions of southern New Jersey there are lands eminently adapted to the dairying industry, contiguous to the markets of New York, Philadelphia, and the large New Jersey cities. In these localities herds of cattle have been repeatedly established, but the attacks by swarms of mosquitoes have reduced the yield in milk to such an extent as to make the animals unprofitable and dairying has been abandoned for occupations which are normally less remunerative. The condition of thoroughbred race horses at the great racing centers of Sheepshead Bay, Long Island, was so impaired by the attacks of mosquitoes as to induce those interested to spend many thousands of dollars a few years ago in an effort to abate the pest.

All over the United States, for these insects and for the house fly as well, it has become necessary, at great expense, to screen habitations. The cost of screening alone must surely exceed $10,000,000 per annum.

MALARIA.

The West Coast of Africa, portions of India, and many other tropical regions have always, at least down to the present period, been practically uninhabitable by civilized man owing to the presence of pernicious malaria. The industrial and agricultural development of Italy has been hindered to an incalculable degree by the prevalence of malaria in the southern half of the Italian peninsula, as well as in the velley of the Po and elsewhere. The introduction and spread of this disease in Greece is stated by Ronald Ross (and with strong reasons) to have been largely responsible for the progressive physical degeneration of one of the strongest races of the earth.

In the United States malaria, if not endemic, was early introduced. The probabilities are that it was endemic, and it is believed that the cause of failure of the early colonies in Virginia was due to this disease. It is certain that malaria retarded in a marked degree the advance of civilization over the North American Continent, and particularly was this the case in the march of the pioneers throughout the Middle West and throughout the Gulf States to the land west to and beyond the Mississippi. In many large regions once malarious the disease has lessened greatly in frequency and virulence owing to the reclamation of swamp areas and the lessening of the number of the possible breeding places of the malarial mosquitoes, but it is still enormously prevalent, particularly in the Southern States. There are many regions in the North where malaria is unknown, but in some of these localities *Anopheles* mosquitoes breed, and the absence of malaria means simply that malarial patients have not entered the regions at such time of the year as might produce a spread of the malady. It has happened again and again that in communities where malaria was previously unknown it has suddenly made its appearance and spread in a startling manner. These cases are sometimes to be explained, as happened in Brookline, Mass., by the introduction of Italian laborers, some of whom were malarious, to work upon the reservoir, or, as happened at a fashionable summer resort near New York City, by the appearance of a coachman who had had malaria elsewhere and suffered relapse at that place. In such ways, with a rapidly increasing population, malaria is still rapidly spreading in this country.

To attempt an estimate of the economic loss from the prevalence of malaria in the United States is a most difficult task. Prof. Irving Fisher, of Yale University, in one of his papers before the recent International Tuberculosis Congress, declared that tuberculosis costs the people of the United States more than $1,000,000,000 per year. In this estimate Professor Fisher considered the death rate for consumption, the loss of the earning capacity of the patients, the period of invalidism, and the amount of money expended in the care of the sick, together with other factors. In making these estimates he had a much more definite basis than can be gained for malaria. The death rate from malaria is comparatively small, and is apparently decreasing. Exact figures for the whole country are not available. From a table comprising 22 cities it appears that two-thirds of the deaths from malaria occur in the South, one-third only in the North. The death rates, by States, are available only for the following registration States: California, Colorado, Connecticut, District of Columbia, Indiana, Maine, Maryland, Massachusetts, Michigan, New Hampshire, New York, New Jersey, Pennsylvania, Rhode Island, South Dakota, and Vermont, all of which are Northern States. For these States the census reports from 1900 to 1907, inclusive, give the following death rates:

Year.	Number per 100,000 population.	Deaths.
1900	7.9	2,434
1901	6.3	1,791
1902	5.4	1,738
1903	4.3	1,410
1904	4.2	1,391
1905	3.9	1,321
1906	3.5	1,415
1907	2.8	1,166
		12,666

Estimating from the preceding table the average annual death rate at 4.8 per 100,000 population, and considering that the registration area includes only 16 of the Northern States (assuming fairly, however, that the death rate in the other Northern States is the same), it seems reasonably safe to conclude that the death rate from malaria for the whole United States must surely amount to 15 per 100,000. It is probably greater than this, since the statistics from the South are city statistics, and malaria is really a country disease. This would give an annual loss by death from malaria of nearly 12,000 and a total number of deaths for the eight-year period (1900–1907) of approximately 96,000.

But with malaria, perhaps as with no other disease, does the death rate fail to indicate the real loss from the economic point of view. A man may suffer from malaria throughout the greater part of his life, and his productive capacity may be reduced by from 50 to 75 per cent, and yet ultimately he may die from some entirely different cause. In fact the predisposition to death from other causes brought about by malaria is so marked that if in the collection of vital statistics it were possible to ascribe the real influence upon mortality that malaria possesses, this disease would have a very high rank in mortality tables. Writing of tropical countries, Sir Patrick Manson states that malaria causes more deaths and more predisposition to death by inducing cachectic states disposing to other affections than all the other parasites affecting mankind together. Moreover, it has been shown that the average life of the worker in malarious places is shorter and the infant mortality higher than in healthy places.

But aside from this vitally important aspect of the subject the effect of malaria in lessening or destroying the productive capacity of the individual is obviously of the utmost importance, and upon the population of a malarious region is enormous, even under modern conditions and in this country. It has been suggested that the depopulation of the thickly settled Roman Campagna was due to the sudden introduction of malaria by the mercenaries of Sylla and Marius. Celli, in 1900, states that owing to malaria about 5,000,000 acres of land in Italy remain not uncultivated, but certainly very imperfectly cultivated. Then, also, in further example, in quite recent years malaria entered and devastated the islands of Mauritius and Reunion, practically destroying for a time the productiveness of these rich colonies of Great Britain and France.

Creighton, in his article on Malaria in the Encyclopedia Britannica, states that this disease "has been estimated to produce one-half of the entire mortality of the human race; and inasmuch as it is the most frequent cause of sickness and death in those parts of the globe that are most densely populated, the estimate may be taken as at least rhetorically correct."[a]

Is it possible to make any close estimate of the relation between the number of deaths from malaria and the number of cases of the same malady? No perfectly sound basis for such an estimate is apparent. In the English translation of Celli's work on "Malaria according to the new researches," published in London in 1900, it is stated that the mortality from malaria in Italy from 1887 to 1898 varied from 21,033 in the first-named year to 11,378 in the last named, and the mean mortality for the period is assumed to be about 15,000. In

---

[a] See Darwinism and Malaria by R. G. Eccles, M. D., Medical Record, New York, January 16, 1909, pp. 85–93.

1896 a count of the patients in the hospitals in Rome was made, and the mortality rate of 7.75 per thousand of the actual patients was established. Calculating, then, on this basis and at this rate the number of cases per year for Italy was placed at about 2,000,000. According to this estimate and with the average mortality for the United States of 12,000, as above indicated, the approximate number of cases for the United States would be about 1,550,000. It seems obvious, however, that Celli, in using the basis of hospital patients only, must have underestimated the number of cases for the kingdom, since of the people in the country suffering from malaria the proportion entering the hospital must be relatively small. Therefore the death rate from malaria of malarial patients in the hospital must be greater than the death rate from malaria of the people who suffer from this disease in the whole country.

In fact so great must this discrepancy necessarily be that it would not seem at all unlikely to the writer if the number of persons suffering from malaria in Italy were in reality nearer 3,000,000 than 2,000,000. The same argument will hold for the United States, and the more especially so since, as a rule, malaria in this country is of a lighter type than in Italy, in fact an estimate of 3,000,000 cases of malaria in the United States annually is probably by no means too high. It will not be an exaggeration to estimate that one-fourth of the productive capacity of an individual suffering with an average case of malaria is lost, and accepting this as a basis, and including the loss through death, the cost of medicines, the losses to enterprises in malarious regions through the difficulty of securing competent labor and other factors, it is safe to place the annual loss to the United States from malarial disease under present conditions at not less than $100,000,000 annually. Celli has shown that in Italy the great railway industries, for example, feel the effect of malaria greatly. According to accurate calculations one company alone, for 1,400 kilometers of railway and for 6,416 workmen in malarious zones, spends on account of malaria 1,050,000 francs a year. The same writer states that the army in Italy from 1877 to 1897 had more than 300,000 cases of malaria.

The loss to this country in the way of retardation of the development of certain regions owing to the presence of malaria is extremely great. Certain territory containing most fertile soil and capable of the highest agricultural productiveness is practically abandoned. With the introduction of proper drainage measures and antimosquito work of other character, millions of acres of untold capacity could be released from the scourge at a comparatively slight expenditure. These regions in the absence of malaria would have added millions upon millions to the wealth of the country. Drainage measures are now being initiated by the Government. Parties of engineers are being sent by the Interior Department to make preliminary drainage surveys in the most prominent of these potentially productive regions. The following statement concerning the effect of malaria on the progress of this work has been made to the writer by Dr. George Otis Smith, Director of the United States Geological Survey:

> In one of the Southern States 11 topographic parties have been at work during the past field season. The full quota for these parties would be 55 men, but I believe that something over 100 men have been employed at different

times during the season. While I have not exact figures before me, I feel warranted in the statement that at least 95 per cent of these employees have been sick for periods ranging from a few days up to two weeks in the hospital. Many of them have been able later to return to work, but at least 30 per cent had to leave the field permanently. By reason of this sickness the efficiency of the parties was reduced, at a very conservative estimate, by 25 per cent.

In my recent visit in this field I found 1 man sick in each of the parties I saw, and 1 man who had just returned from the hospital leaving the field for good. A similar state of things was reported from the other parties. I regard the sickness as practically all of a malarial nature, as extreme care was taken in all the camps to use nothing but boiled water, except in a few instances, where artesian water from great depths was available. In all the camps the tents have been screened, and in every case where the topographer has lived for any time "on the country" there has been infection. As illustrating the value of the precautions generally taken by our camp parties I might cite the fact that last year in West Virginia, with 30 men living in a camp, with typhoid fever prevalent in the neighborhood, no cases developed, while with 6 men living on the country, where the same care could not be taken regarding the water supply, 2 cases of typhoid developed.

In estimating the weight of Doctor Smith's statement it must be borne in mind that the men of his field parties are exceptionally intelligent and prepared to take all ordinary precautions.

Throughout the region in question malaria is practically universal. The railroads suffer, and at the stations throughout the territory it is practically impossible to keep operators steadily at work. This reduction in efficiency in the surveying parties and in the local railroad officials is, moreover, probably very considerably less than the reduction in the earning capacity of the entire population, which, however, is necessarily scanty.

In an excellent paper entitled "The relation of malaria to agricultural and other industries of the South," published in the Popular Science Monthly for April, 1903, Prof. Glenn W. Herrick, then of the College of Agriculture of Mississippi, after a consideration of the whole field, concludes that malaria is responsible for more sickness among the white population of the South than any other disease to which that section is now subject. The following forcible statement, referring to the States of Louisiana, Mississippi, Alabama, Georgia, and South Carolina, is in Professor Herrick's words:

We must now consider briefly what 635,000 or 1,000,000 cases of chills and fevers in one year mean. It is a self-evident truth that it means well for the physician; but for laboring men it means an immense loss of their time, together with the doctors' fees in many instances. If members of their families other than themselves be affected, it may also mean a loss of time, together with the doctors' fees. For the employer it means the loss of labor at a time perhaps when it would be of greatest value. If it does not mean the actual loss of labor to the employer, it will mean a loss in the efficiency of his labor. To the farmers it may mean the loss of their crops by want of cultivation. It will always mean the noncultivation or imperfect cultivation of thousands of acres of valuable land. It means a listless activity in the world's work that counts mightily against the wealth-producing power of the people. Finally it means from two to five million or more days of sickness with all its attendant distress, pain of body, and mental depression to some unfortunate individuals of those five States.

Referring to the Delta region in Mississippi, which lies along the Mississippi River in the western part of the State extending from the mouth of the Yazoo River north nearly to the Tennessee line, Herrick says that it is the second best farming land in the world, having only one rival, and that is the Valley of the Nile. Herrick says:

Still this land to-day, or at least much of it, can be bought at $10 to $20 an acre. Thousands of acres in this region are still covered with the primeval forests, and bears and deer still roaming there offer splendid opportunities for the chase, as evidenced by the late visit of our ex-Chief Executive to those regions for the purpose of hunting. Why is not this land thickly settled? And why is it not worth from $200 to $500 an acre? If it produces from one to two or more bales of cotton on an acre, and it does, it ought to be worth the above-named figures. A bale of cotton to the acre can be produced for $13, leaving a net profit of $20 to $40 for each bale, or $40 to $80 or more for each acre of land cultivated. Moreover, this land has been doing that for years, and will do it for years to come, without the addition of one dollar's worth of fertilizer. Land that will produce a net profit of $40 to $80 an acre is a splendid investment at $100, $200, or even $300 an acre. Yet this land does not sell in the market for anything like so much, because the demand is not sufficient, for white people positively object to living in the Delta on account of malarial chills and fevers. A man said to me not long ago that he would go to the Delta that day if he were sure that his own life or the lives of the members of his family would not be shortened thereby. There are thousands exactly like him, and the only reason that these thousands do not go there to buy lands and make homes is on account of chills and fevers. But there is a time coming, and that not far distant, when malaria in the Delta will not menace the would-be inhabitants. When that time comes it will be the richest and most populous region in the United States.

Malaria is a preventable disease. It is possible for the human species to live, thrive, and produce in malarious regions, but at a very considerable inconvenience and expense. The Italian investigators, and especially Celli and his staff, have shown that by screening the huts of the peasants on the Roman Campagna and by furnishing field laborers with veils and gloves when exposed to the night air it is possible even in that famous hotbed of malaria to conduct farming operations with a minimum of trouble from the disease. Moreover, Koch and his assistants in German East Africa have shown that it is possible, by stamping out the disease among human beings by the free use of medicine, to reach a point where there is small opportunity for malarial mosquitoes to become infected. Moreover, the work of the parties sent out by the Liverpool School of Tropical Medicine and other English organizations to the west coast of Africa has shown that by proper treatment of malarial-mosquito breeding pools the pernicious coast fever may be greatly reduced. Again, the work of Englishmen in the Malay Federated States has shown that large areas may be practically freed from malaria. The most thorough and the most satisfactory of all measures consists in abolishing the breeding places of malarial mosquitoes. In regions like the Delta of Mississippi this involves extensive and systematic drainage, but in very many localities where the breeding places of the *Anopheles* mosquitoes can be easily eradicated, where they are readily located and are so circumscribed as to admit of easy treatment, it is possible to rid the section from malaria at a comparatively slight expense.

With a general popular appreciation of the industrial losses caused primarily by the malarial mosquito and, secondarily, by the nonmalarial carrying forms, as indicated in the opening paragraphs, it is inconceivable that the comparatively inexpensive measures necessary should not be undertaken by the General Government, by the state governments, and by the boards of health of communities, just as it is inconceivable that the individual should suffer from malaria and from the attacks of other mosquitoes when he has individual preventives and remedies at hand. Large-scale drainage measures by the General Government involving large sections of valuable territory have been planned and are practically under way; certain States, notably New Jersey and New York, are beginning to work; communities all over the country through boards of health are also beginning to take notice, while popular education regarding the danger from mosquitoes and in regard to remedial measures is rapidly spreading. But all of this interest should be intensified, and the importance of the work should be displayed in the most emphatic manner, and relief from malarial and other mosquito conditions should be brought about as speedily as possible.

A few excellent examples of antimalarial work may be instanced. The latest reports on the measures taken to abolish malaria from Klang and Port Swettenham in Selangor, Federated Malay States, indicate the most admirable results. These measures were undertaken first in 1901 and 1902 and have been reported upon from time to time in the Journal of Tropical Medicine. The expenditure undertaken by the Government with a view to improving the health of the inhabitants of these towns has been fully justified by the results, which promise to be of permanent value. The total expenditure for the town of Klang, down to the end of 1905, was £3,100, and the annual permanent expenditure is about £60 for clearing earth drains and £210 for town gardeners. For Port Swettenham the total expenditure to the end of 1905 was £7,000, and the annual cost of keeping up the drains, etc., is approximately £40 for clearing earth drains and £100 for town gardeners.

The careful tabulation of cases and deaths and of the results of the examination of blood of children in especially drained areas indicates the following conclusions: (1) Measures taken systematically to destroy breeding places of mosquitoes in these towns, the inhabitants of which suffered terribly from malaria, were followed almost immediately by a general improvement in health and decrease in death rate. (2) That this was due directly to the work carried out and not to a general dying out of malaria in the district is clearly shown by figures, pointing out that while malaria has practically ceased to exist in the areas treated, it has actually increased to a considerable extent in other parts of the district where antimalarial measures have not been undertaken.

The statistics for 1905 are even more favorable than those for 1902, which give a very strong evidence in favor of the permanent nature of the improvement carried out. In fact, it seems that malaria has been permanently stamped out at Klang and Port Swettenham by work undertaken in 1901, and this experience in the Malay States should be of value to those responsible for the health of communities similarly situated in many other parts of the world.

Another striking example of excellent work of this kind is found in the recently published report on the suppression of malaria in Ismaïlia, issued under the auspices of the Compagnie Universelle du Canal Maritime de Suez. Ismaïlia is now a town of 8,000 inhabitants. It was founded by De Lesseps in April, 1862, on the borders of Lake Timsah, which the Suez Canal crosses at middistance between the Red Sea and the Mediterranean. Malarial fever made its appearance in very severe form in September, 1877, although the city had up to that time been very healthful, and increased so that since 1886 almost all of the inhabitants have suffered from the fever. In 1901 an attempt to control the disease was made on the mosquito basis, and this attempt rapidly and completely succeeded, and after two years of work all traces of malaria disappeared from the city. The work was directed not only against *Anopheles* mosquitoes, but against other *Culicids*, and comprised the drainage of a large swamp and the other usual measures. The initial expense amounted to 50,000 francs, and the usual annual expenses since have amounted to about 18,300 francs.

The results may be summarized about as follows: Since the beginning of 1903 the ordinary mosquitoes have disappeared from Ismaïlia. Since the autumn of 1903 not a single larva of *Anopheles* has been found in the protected zone, which extends to the west for a distance of 1,000 meters from the first houses in the Arabian quarter, and to the east for a distance of 1,800 meters from the first houses in the European quarter. After 1902 malarial fever obviously began to decrease, and since 1903 not a single new case of malaria has been found in Ismaïlia.

A very efficient piece of antimalarial work was accomplished in Habana during the American occupation of 1901 and 1902, incidental in a way to the work against yellow fever. An *Anopheles* brigade of workmen was organized under the sanitary officer, Doctor Gorgas, for work along the small streams, irrigated gardens, and similar places in the suburbs, and numbered from 50 to 300 men. No extensive draining, such as would require engineering skill, was attempted, and the natural streams and gutters were simply cleared of obstructions and grass, while superficial ditches were made through the irrigated meadows. Among the suburban truck gardens *Anopheles* bred everywhere, in little puddles of water, cow tracks, horse tracks, and similar depressions in grassy ground. Little or no oil was used by the *Anopheles* brigade, since it was found in practice a simple matter to drain these places. At the end of the year it was very difficult to find water containing mosquito larvæ anywhere in the suburbs, and the effect upon malarial statistics was striking. In 1900, the year before the beginning of the mosquito work, there were 325 deaths from malaria; in 1901, the first year of the mosquito work, 171 deaths; in 1902, the second year of mosquito work, 77 deaths. Since 1902 there has been a gradual though slower decrease, as follows: 1903, 51; 1904, 44; 1905, 32; 1906, 26; 1907, 23. These results, although less striking than those from Ismaïlia, involved a smaller expense in money and show surely an annual saving of 300 lives, and undoubtedly a corresponding decrease in the number of malarial cases, which may be estimated upon our earlier basis at something less than 40,000.

YELLOW FEVER.

Yellow fever has prevailed endemically throughout the West Indies and in certain regions on the Spanish Main virtually since the discovery of America. The Barbados, Jamaica, and Cuba suffered epidemics before the middle of the seventeenth century. There were outbreaks in Philadelphia, Charleston, and Boston as early as 1692, and for a hundred years there were occasional outbreaks, culminating in the great Philadelphia epidemic of 1793. Northern cities were able by rigid quarantine measures to prevent great epidemics after the early part of the nineteenth century, but from the West Indies the disease was occasionally introduced and prevailed from time to time epidemically in the Southern States. In 1853 it raged throughout this region, New Orleans alone having a mortality of 8,000. The last widespread epidemic occurred in 1878, chiefly in Louisiana, Alabama, and Mississippi, but spreading up the Mississippi Valley as far as Cairo, Ill., attacking with virulence the city of Memphis, Tenn. In this year there were 125,000 cases and 12,000 deaths. In 1882 there were 192 deaths at Pensacola; in 1887, 62 deaths in the Southern States; in 1893, 52 deaths; in 1897, 484; in 1898, 2,456 cases, with 117 deaths; in 1903, 139 deaths were recorded, mostly at Laredo, Tex.; and in 1905 there was a serious outbreak at New Orleans and in neighboring towns, including one locality in Mississippi, in which 911 deaths were recorded for the whole country.

The actual loss of life from yellow fever during all these years, when compared to the loss from other diseases, has been comparatively slight, but the death rate is perhaps the most insignificant feature of the devastation which yellow-fever epidemics have produced, and the disease itself has been but a small part of the affliction which it has brought to the Southern States. The disease once discovered in epidemic form, the whole country has become alarmed; commerce in the affected region has come virtually to a standstill; cities have been practically deserted; people have died from exposure in camping out in the highlands; rigid quarantines have been established; innocent persons have been shot while trying to pass these quarantine lines; all industry for the time has ceased. The commerce of the South during the epidemic of 1878, for example, fell off 90 per cent, and the hardships of the population can not be estimated in monetary terms. With such industrial and commercial conditions existing from Texas to South Carolina, many industries at the North have suffered, and, in fact, the effect of a yellow-fever summer in the South has been felt not only all over the United States, but in many other portions of the world.

All these conditions, as bad as they have been, do not sum up the total loss to the national prosperity during past years. Cities like Galveston, New Orleans, Mobile, Memphis, Jacksonville, and Charleston, subject to occasional epidemics, as they have been in the past, have not prospered as they should. Their progress has been greatly impeded by this one cause, and thus the industrial development of the entire South has been greatly retarded.

Physicians had been theorizing about the cause of yellow fever from the time when they began to treat it. It was thought by many that it was carried in the air; by others that it was conveyed by the clothing, bedding, or other articles which had come in contact with a yellow-fever patient. There were one or two early suggestions of the agency of mosquitoes, but practically no attention was paid to them, and they have been resurrected and considered significant only since the beginning of the present century. With the discovery of the agency of micro-organisms in the causation of disease, a search soon began for some causative germ. Many micro-organisms were found in the course of the autopsies and many claims were put forth by investigators. All of these, however, were virtually set at rest by Sternberg in his "Report on the Etiology and Prevention of Yellow Fever," published in 1890, but a claim made by Sanarelli in June, 1897, for a bacillus which he called *Bacillus icteroides* received considerable credence, and in 1899 it was accepted in full by Wasden and Geddings, of the Marine-Hospital Service, who reported that they had found this bacillus in 13 or 14 cases of yellow fever in the city of Habana. There is no evidence, however, that this bacillus has anything to do with yellow fever. In 1881 Finlay, of Habana, proposed the theory that yellow fever whatever its cause may be is conveyed by means of *Culix* (now *Stegomyia*) *fasciatus* (now *calopus*). Subsequently he published several important papers in which his views were modified from time to time, and in the course of which he mentioned experiments with 100 individuals, producing 3 cases of mild fever. None of the cases, however, was under his full control, and the possibility of other methods of gaining the disease was not excluded. Therefore his theory, while it was received with interest, was not considered to be proved.

In 1890 came the beginning of the true demonstration. An army board was appointed by Surgeon-General Sternberg for the purpose of investigating the acute infectious diseases prevailing in the island of Cuba. The result achieved by this board, consisting of Reed, Carroll, Lazear, and Agramonte, was a demonstration that yellow fever is carried by *Stegomyia calopus*, and their ultimate demonstration was so perfect as to silence practically all expert opposition. The Third International Sanitary Convention of the American Republics unanimously accepted the conclusion that yellow fever is carried by this mosquito and that the *Stegomyia* constitutes the only known means by which the disease is spread. To-day, after abundant additional demonstration, the original contention of Reed, Carroll, and Agramonte (Lazear having died in the course of the experiments) is a part of the accepted knowledge of the medical world. The importance of the discovery can not be overestimated, and its first demonstration was followed by antimosquito measures in the city of Habana, undertaken, under the direction of Gorgas, with startling results.

Yellow fever had been endemic in Habana for more than one hundred and fifty years, and Habana was the principal source of infection for the rest of Cuba. Other towns in the island could have rid themselves of the disease if they had not been constantly reinfected from Habana. By ordinary sanitary measures of cleanliness, improved drainage, and similar means the death rate of the city was improved from an average of 40 per thousand under Spanish rule to 22 per thousand in 1900, but these measures had no effect upon yellow fever, this disease increasing as the nonimmune population following the Spanish war increased.

Stegomyia calopus was established as the carrier of the fever early in 1901, and then antimosquito measures were immediately begun. Against adult mosquitoes no general measures were attempted, although screening and fumigation were carried out in quarters occupied by yellow-fever patients. It was found that the *Stegomyia* bred principally in the rain-water collections in the city itself. The city was divided into about 30 districts, and to each district an inspector and two laborers were assigned—each district containing about a thousand houses. An order was issued by the mayor of Habana requiring all collections of water to be so covered that mosquitoes could not have access, a fine being imposed in cases where the order was not obeyed. The health department covered the rainwater barrels of poor families at public expense. All cesspools were treated with petroleum. All receptacles containing fresh water which did not comply with the law were emptied and on the second offense destroyed. The result of this work thoroughly done was to wipe out yellow fever in Habana, and for four years there was not a case in Habana or in Cuba.

In what is termed the "New Orleans epidemic of 1905," a striking illustration of the value of this recently acquired mosquito-transmission knowledge is seen. The presence of yellow fever in the city was first recognized about the 1st of July, but it was the 12th of August before the Public Health and Marine-Hospital Service was put in complete control of the situation. By that time the increase in new cases and deaths rendered it practically certain that the disease was as widespread as during the terrible epidemic of 1878. There had been up to that date 142 deaths from a total of 913 cases, as against 152 deaths from a total of 519 cases in 1878. The Public Health and Marine-Hospital Service, under Doctor White, took hold of the situation with energy, basing its measures almost entirely upon a warfare against *Stegomyia calopus.* The disease began almost immediately to abate, and the result at the close of the season indicated 460 deaths, as against 4,046 in 1878, a virtual saving of over 3,500 lives. The following table of deaths from yellow fever in New Orleans from 1847 to 1905 points out most strikingly the value of this antimosquito work:

Comparative table of deaths from yellow fever in New Orleans.

Months.	1847.	1848.	1853.	1854.	1855.	1858.	1867.	1878.	1905.
May	....	....	2						
June	....	4	31	2	5	2	3	....	....
July	74	33	1,521	29	382	132	11	26	35
August	965	200	5,133	532	1,286	1,140	255	1,025	236
September	1,100	467	982	1,234	874	2,204	1,637	1,780	107
October	198	126	147	490	97	1,137	1,072	1,065	59
November	12	20	28	131	19	224	103	147	23
December	10	....	4	7	7	15	26	3	....
Months unknown	445	22	....	....	....	....	....	....	....
Total	2,804	872	7,848	2,425	2,670	4,854	3,107	4,046	460

The epidemics of 1848, 1854, and 1855 are least comparable with that of 1905, because they immediately succeed severe epidemics to which were due very many immunes.

Population of New Orleans by United States Census: 130,565 in 1850; 168,675 in 1860; 191,418 in 1870; 216,090 in 1880; and 287,104 in 1900.

WORK ON THE ISTHMUS OF PANAMA.

The United States Government has very properly used the services of Colonel Gorgas, who was in charge of the eminently successful work at Habana, by appointing him chief sanitary officer of the Canal Zone during the digging of the canal. In 1904 active work was begun, and Colonel Gorgas was fortunate in having the services of Mr. Le Prince, who had been chief of his mosquito brigades in Habana, and therefore was perfectly familiar with antimosquito methods. In Panama, the population had depended principally upon rain water for domestic purposes, so that every house had cisterns, water barrels, and such receptacles for catching and storing rain water. The city was divided into small districts with an inspector in charge of each district. This inspector was required to cover his territory at least twice a week and to make a report upon each building with regard to its condition as to breeding places of mosquitoes. All the cisterns, water barrels, and other water receptacles in Panama were covered as in Habana, and in the water barrels spigots were inserted so that the covers would not have to be taken off. Upon first inspection, in March, 4,000 breeding places were reported. At the end of October less than 400 containing larvæ were recorded. This gives one a fair idea of the consequent rapid decrease in the number of mosquitoes in the city. These operations were directed primarily against the yellow-fever mosquito, and incidentally against the other common species that inhabit rain-water barrels. Against the *Anopheles* in the suburbs the same kind of work was done as in Habana, with exceptionally good results.

The same operations were carried on in the villages between Panama and Colon. There are some twenty of these, running from 500 to 3,000 inhabitants each. Not a single instance of failure has occurred in the disinfection of these small towns, and the result of the work has been the apparent elimination of yellow fever and the very great reduction of malarial fever. The remarkable character of these results can only be judged accurately by comparative methods. It is well known that during the French occupation there was an enormous mortality among European employees, and this was a vital factor in the failure of the work. Exact losses can not be estimated, since the work was done under 17 different contractors. These contractors were charged $1 a day for every sick man to be taken care of in the hospital of the company. Therefore it often happened that when a man became sick his employer discharged him so that he would not have to bear the expense of hospital charges. There was no police patrol of the territory. A great many of these men were found to have died along the roadside while endeavoring to find their way to the city of Panama. Colonel Gorgas has stated that the English consul, who was at the Isthmus during the period of the French construction, is inclined to think that more deaths of employees occurred out of the hospital than in it. The old superintendent of the French hospital states that one day 3 of the medical staff died from yellow fever, and in the same month 9 of the medical staff. Thirty-six Roman Catholic sisters were brought over as nurses, of whom 24 died of yellow fever. On one vessel 18 young French engineers came over, and within a month all but 1 died.

Now that the relation of the mosquito to yellow fever is well understood, it was found during the first two years under Colonel Gorgas that although there were constantly one or more yellow-fever cases in the hospital, and although the nurses and physicians were all nonimmunes, not a single case of yellow fever was contracted in that way. The nurses never seemed to consider that they were running any risk in attending yellow-fever cases night and day in screened wards, and the wives and families of officers connected with the hospital lived about the grounds, knowing that yellow fever was constantly being brought into the grounds and treated in near-by buildings. Americans, sick from any cause, had no fear of being treated in beds immediately adjoining those of yellow-fever patients. Colonel Gorgas and Doctor Carter lived in the old ward used by the French for their officers, and Colonel Gorgas thinks it safe to say that more men had died from yellow fever in that building under the French régime than in any other building of the same capacity at present standing. He and Doctor Carter had their wives and children with them, which would formerly have been considered the height of recklessness; but they looked upon themselves, under the now recognized precautions, almost as safe as they would have been in Philadelphia or Boston.

No figures of actual cost of the antimosquito work, either in Habana or in the Panama Canal Zone, are accessible to the writer, but it is safe to say that it was not exorbitant, and that it was not beyond the means of any well-to-do community in tropical regions.

THE TYPHOID FLY, COMMONLY KNOWN AS THE "HOUSE FLY."

The name "typhoid fly" is here proposed as a substitute for the name "house fly," now in general use. People have altogether too long considered the house fly as a harmless creature, or, at the most, simply a nuisance. While scientific researches have shown that it is a most dangerous insect from the standpoint of disease, and while popular opinion is rapidly being educated to the same point, the retention of the name "house fly" is considered inadvisable as perpetuating in some degree the old ideas. Strictly speaking, the term "typhoid fly" is open to some objection as conveying the erroneous idea that this fly is solely responsible for the spread of typhoid; but considering that the insect is dangerous from every point of view, and that it is an important element in the spread of typhoid, it seems advisable to give it a name which is almost wholly justified and which conveys in itself the idea of serious disease. Another repulsive name that might be given to it is the "manure fly;" but recent researches have shown that it is not confined to manure as a breeding place, although perhaps the great majority of these flies are so propagated. For the end in view "typhoid fly" is considered the best name.

The true connection and the true scientific evidence regarding the rôle of the so-called "house fly" with typhoid fever has only recently been worked out. Celli, in 1888, fed flies with pure cultures of the *Bacillus typhi-abdominalis*, and examined their contents and dejections microscopically and culturally. Inoculations of animals were also made, proving that the bacilli which passed through flies were virulent. Dr. George M. Kober, who is familiar with Celli's researches, in his report on the prevalence of typhoid fever in the District of Columbia, published in 1895, called especial attention to the danger of the contamination of food supplies by flies coming from the excreta of typhoid patients. The prevalence of typhoid fever in the concentration camps of the United States Army in the summer of 1898 brought about the appointment of an army typhoid commission, consisting of Dr. Walter Reed, U. S. Army; Dr. Victor M. Vaughan, U. S. Volunteers; and Dr. E. O. Shakespeare, U. S. Volunteers. A paper read by Doctor Vaughan before the annual meeting of the American Medical Association at Atlantic City, N. J., June 6, 1900, contained the following conclusions with regard to flies:

27. *Flies undoubtedly served as carriers of the infection.*—My reasons for believing that flies were active in the dissemination of typhoid may be stated as follows:

"*a.* Flies swarmed over infected fecal matter in the pits and then visited and fed upon the food prepared for the soldiers at the mess tents. In some instances where lime had recently been sprinkled over the contents of the pits, flies with their feet whitened with lime were seen walking over the food.

"*b.* Officers whose mess tents were protected by means of screens suffered proportionately less from typhoid fever than did those whose tents were not so protected.

"*c.* Typhoid fever gradually disappeared in the fall of 1898, with the approach of cold weather, and the consequent disabling of the fly.

"It is possible for the fly to carry the typhoid bacillus in two ways. In the first place, fecal matter containing the typhoid germ may adhere to the fly and be mechanically transported. In the second place, it is possible that the typhoid bacillus may be carried in the digestive organs of the fly and may be deposited with its excrement."

There were also many important conclusions which bear upon the fly question. For example, it was shown that every regiment in the United States service in 1898 developed typhoid fever, nearly all of them within eight weeks after assembling in camps. It not only appeared in every regiment in the service, but it became epidemic both in small encampments of not more than one regiment and in the larger ones consisting of one or more corps. All encampments located in the Northern, as well as in the Southern States, exhibited typhoid in epidemic form. The miasmatic theory of the origin of typhoid fever and the pythogenic theory[a] were not supported by the investigations of the commission, but the doctrine of the specific origin of fever was confirmed. The conclusion was reached that the fever is disseminated by the transference of the excretions of an infected individual to the alimentary canals of others, and that a man infected with typhoid fever may scatter the infection in every latrine or regiment before the disease is recognized in himself, while germs may be found in the excrement for a long time after the apparently complete recovery of the patient. Infected water was not an important factor in the spread of typhoid in the national encampments of 1898, but about one-fifth of the soldiers in the national encampments in the United States during that summer developed this disease, while more than 80 per cent of the total deaths were caused by typhoid.

In 1899 the writer began the study of the typhoid or house fly under both country and city conditions. He made a rather thorough investigation of the insect fauna of human excrement, and made a further investigation of the species of insects that are attracted to food supplies in houses. In a paper entitled "A contribution to the study of the insect fauna of human excrement (with especial reference to the spread of typhoid fever by flies)," published in the Proceedings of the Washington Academy of Sciences, Volume II, pages 541–604, December 28, 1900, he showed that 98.8 per cent of the whole number of insects captured in houses throughout the whole country under the conditions indicated above were *Musca domestica*, the typhoid or house fly. He showed further that this fly, while breeding most numerously in horse stables, is also attracted to human excrement and will breed in this substance. It was shown that in towns where the box privy was still in existence the house fly is attracted to the excrement, and, further, that it is so attracted in the filthy regions of a city where sanitary supervision is lax and where in low alleys and corners and in vacant lots excrement is deposited. He stated that he had seen excrement which had been deposited overnight in an alleyway in south Washington swarming with flies under the bright sunlight of a June morning (temperature 92° F.), and that within 30 feet of these deposits were the open windows and doors of the kitchens of two houses kept by poor people, these two houses being only elements in a long row. The following paragraph is quoted from the paper just cited:

---

[a] This theory is founded upon the belief that the colon germ may undergo a ripening process by means of which its virulence is so increased and altered that it may be converted into the typhoid bacillus, or at least may become the active agent in the causation of typhoid fever.

> Now, when we consider the prevalence of typhoid fever and that virulent typhoid bacilli may occur in the excrement of an individual for some time before the disease is recognized in him and that the same virulent germs may be found in the excrement for a long time after the apparent recovery of a patient, the wonder is not that typhoid is so prevalent but that it does not prevail to a much greater extent. Box privies should be abolished in every community. The depositing of excrement in the open within town or city limits should be considered a punishable misdemeanor in communities which have not already such regulations, and it should be enforced more rigorously in towns in which it is already a rule. Such offenses are generally committed after dark and it is often difficult or even impossible to trace the offender; therefore the regulation should be carried even further and require the first responsible person who notices the deposit to immediately inform the police so that it may be removed or covered up. Dead animals are so reported, but human excrement is much more dangerous. Boards of health in all communities should look after the proper treatment or disposal of horse manure, primarily in order to reduce the number of house flies to a minimum, and all regulations regarding the disposal of garbage and foul matter should be made more stringent and should be more stringently enforced.

In the opening sentence of the paragraph just quoted attention was called to the activity of bacilli in excreta passed by individuals after apparent recovery from typhoid. Since the paper in question was published more especial attention has been drawn by medical men to this point, and it has been shown that individuals who are chronic spreaders of the typhoid germs are much more abundant than was formerly supposed. Dr. George A. Soper recently discovered a striking case of this kind in the person of a cook employed successively by several families in the vicinity of New York City, with the result that several cases of typhoid occurred in each of these families. In a paper by Doctor Davies and Professor Walker, read before the Royal Sanitary Institute of London during the present season, the history was given of four personal carriers of typhoid who had communicated the disease to a number of people. These four carriers were detected in one city within a few months, and from this fact it can be argued with justice that such cases are comparatively numerous. This being the case, the danger of unguarded miscellaneous human excreta deposited in city suburbs, in vacant lots, in low alleyways, intensifies to a very marked degree the danger of food contamination with typhoid bacilli by means of the typhoid or house fly. It is well known, too, that the urine of persons who have suffered from typhoid fever often contains typhoid bacilli for several weeks after the patients have recovered; consequently, this also is a source of danger.

The importance of the typhoid fly as a carrier of the disease in army camps, as shown in the Spanish war and in the Boer war and in the camps of great armies of laborers engaged in gigantic enterprises like the digging of the Panama Canal, is obvious, but what has just been stated indicates that even under city conditions the influence of this fly in the spread of this disease has been greatly underestimated. It is not claimed that under city conditions the house fly becomes by this argument a prime factor in the transfer of the disease, but it must obviously take a much higher relative rank among typhoid conveyers than it has hitherto assumed. Perhaps even under city conditions it must assume third rank—next to water and milk.

It is not alone as a carrier of typhoid that this fly is to be feared. In the same way it may carry nearly all intestinal diseases. It is a prime agent in the spreading of summer dysentery, and in this way is unquestionably responsible for the death of many children in summer. One of the earliest accurate scientific studies of the agency of insects in the transfer of human disease was in regard to flies as spreaders of cholera. The belief in this agency long preceded its actual proof. Dr. G. E. Nicholas, in the London Lancet,[a] is quoted by Nuttall as writing, in 1849, when cholera prevailed at Malta:

> My first impression of the possibility of the transfer of the disease by flies was derived from the observation of the manner in which these voracious creatures, present in great numbers and having equal access to the dejections and food of patients, gorged themselves indiscriminately and then disgorged themselves on the food and drinking utensils. In 1850 the *Superb*, in common with the rest of the Mediterranean squadron, was at sea nearly six month. During the greater part of the time she had cholera on board. On putting to sea, the flies were in great force; but after a time they gradually disappeared and the epidemic slowly subsided. On going into Malta Harbor, but without communicating with the shore, the flies returned in greater force and the cholera also with increased violence. After more cruising at sea the flies disappeared gradually with the subsidence of the disease.

Accurate scientific bacteriological observations by Tizzoni and Cattani in 1886 showed definitely active cholera organisms in the dejecta of flies caught in the cholera wards in Bologna. These observations were subsequently verified and extended by Simonds, Offelmann, Macrae, and others.

With tropical dysentery and other enteric diseases practically the same conditions exist. In a report by Daniel D. Jackson to the committee on pollution of the Merchants' Association in New York, published in December, 1907, the results of numerous observations upon the relation of flies to intestinal disease are published, and the relation of deaths from intestinal diseases in New York City to the activity and prevalence of the common house fly is shown not only by repeated observations, but also by an interesting plotting of the curve of abundance of flies in comparison with the plotted curve of abundance of deaths from intestinal diseases, indicating that the greatest numbers of flies occurred in the weeks ending July 27 and August 3; that the deaths from intestinal diseases rose above the normal at the same time at which flies became prevalent, culminated at the same high point, and fell off with slight lag at the time of the gradual falling off of the prevalence of the insects.

Similar studies have been carried on during the summer of 1908 in the city of Washington, and the curve of typhoid fly abundance for the whole city as well as that for a district comprising eight city squares, in which intensive studies have been made both of flies and of disease, will be plotted at the close of the season. At the time of writing this work has not been completed.

---

[a] Volume II, 1873, p. 724.

The typhoid fly also possesses importance as a disseminator of the bacilli of tuberculosis. In a paper by Dr. Frederick T. Lord, of Boston,[a] the following conclusions are reached:

> **1. Flies may ingest tubercular sputum and excrete tubercle bacilli, the virulence of which may last for at least fifteen days.**
>
> **2. The danger of human infection from tubercular flyspecks is by the ingestion of the specks on food. Spontaneous liberation of tubercle bacilli from flyspecks is unlikely. If mechanically disturbed, infection of the surrounding air may occur.**
>
> **As a corollary to these conclusions it is suggested that—**
>
> **3. Tubercular material (sputum, pus from discharging sinuses, fecal matter from patients with intestinal tuberculosis, etc.) should be carefully protected from flies lest they act as disseminators of the tubercle bacilli.**
>
> **4. During the fly season greater attention should be paid to the screening of rooms and hospital wards containing patients with tuberculosis and laboratories where tubercular material is examined.**
>
> **5. As these precautions would not eliminate fly infection by patients at large, foodstuffs should be protected from flies which may already have ingested tubercular material.**

From all these facts it appears that the most important part played by the typhoid fly or house fly in the human economy is to carry bacteria from one place to another. The following table and comments are taken from Bulletin No. 51 (April, 1908) of the Storrs Agricultural Experiment Station, Storrs, Conn., entitled "Sources of Bacteria in Milk," by W. M. Esten and C. J. Mason.

Sources of bacteria from flies.

Date.	Source.	Total number.	Total acid bacteria.	Rapid liquefying bacteria.	Slow liquefying bacteria.	Bacterium lactis acidi (Group A, Class 1).	Coli-aerogenes (Group A, Class 2).

	Average per cent of 256 flies, experiments (*d*), (*e*), and (*f*)..	....	25	....	8	7	18

[a] 2,200 mold spores.

From the above table the bacterial population of 414 flies is pretty well represented, the domestic fly passing from a disgusting nuisance and troublesome pest to a reputation of being a dangerous enemy to human health. A species of mosquito has been demonstrated to be the cause of the spread of malaria. Another kind of mosquito is the cause of yellow fever, and now the house fly is considered an agency in the distribution of typhoid fever, summer complaint, cholera infantum, etc.

The numbers of bacteria on a single fly may range all the way from 550 to 6,600,000. Early in the fly season the numbers of bacteria on flies are comparatively small, while later the numbers are comparatively very large. The place where flies live also determines largely the numbers that they carry. The average for the 414 flies was about 1,250,000 bacteria on each. It hardly seems possible for so small a bit of life to carry so large a number of organisms. The method of the experiment was to catch the flies from the several sources by means of a sterile fly net, introduce them into a sterile bottle, and pour into the bottle a known quantity of sterilized water, then shake the bottle to wash the bacteria from their bodies, to simulate the number of organisms that would come from a fly in falling into a lot of milk. In experiments (*d*), (*e*), and (*f*) the bacteria were analyzed into four groups. The objectionable class, coli-aerogenes type, was 2½ times as abundant as the favorable acid type. If these flies stayed in the pigpen vicinity there would be less objection to the flies and the kinds of organisms they carry, but the fly is a migratory insect, and it visits everything "under the sun." It is almost impossible to keep it out of our kitchens, dining rooms, cow stables, and milk rooms. The only remedy for this rather serious condition of things is to remove the pigpen as far as possible from the dairy and dwelling house. Extreme care should be taken in keeping flies out of the cow stable, milk rooms, and dwellings. Flies walking over our food are the cause of one of the worst contaminations that could occur from the standpoint of cleanliness and the danger of distributing disease germs.

The danger of the typhoid or house fly in the carriage of disease has thus been abundantly demonstrated. Further than this, it is an intolerable nuisance. With mosquitoes, it necessitates an annual outlay for window and door screens in the United States of not less than $10,000,000. As a carrier of disease it causes a loss of many millions of dollars annually. Dr. G. M. Kober, in a paper prepared for the governors' conference on the conservation of natural resources, held at the White House in May, 1908, entitled "The conservation of life and health by improved water supply," presented figures showing that the decrease in the vital assets of the country through typhoid fever in a single year is more than $350,000,000. The house fly, as an important agent in the spread of this disease, is responsible for a very considerable portion of this decrease in vital assets. As an agency in the spread of other intestinal diseases, this sum must be greatly increased, and yet the fly is allowed to breed unrestricted all over the United States; it is allowed to enter freely the houses of the great majority of our people; it is allowed to spread bacteria freely over our food supplies in the markets and in the kitchens and dining rooms of private houses; and, to use the happy phraseology of Dr. Theobald Smith, "When we go into public restaurants in midsummer, we are compelled to fight for our food with the myriads of house flies which we find there, alert, persistent, and invincible."

Even if the typhoid or house fly were a creature difficult to destroy, the general failure on the part of communities to make any efforts whatever to reduce its numbers could properly be termed criminal neglect, but since, as will be shown, it is comparatively an easy matter to do away with the plague of flies, this neglect becomes an evidence of ignorance or of a carelessness in regard to disease-producing filth which to the informed mind constitutes a serious blot on civilized methods of life.

Strange as it may seem, an exhaustive study of the conditions which produce house flies in numbers has never been made. The life history of the insect in general was, down to 1873, mentioned in only three European works and few exact facts were given. In 1873 Dr. A. S. Packard, then of Salem, Mass., studied the transformations of the insect and gave descriptions of all stages, showing that the growth of a generation from the egg state to the adult occupies from ten to fourteen days.

In 1895 the writer traced the life history in question, indicating that 120 eggs are laid by a single female, and that in Washington in midsummer a generation is produced every ten days. Although numerous substances were experimented with, he was able to breed the fly only in horse manure. Later investigations indicated that the fly will breed in human excrement and in other fermenting vegetable and animal material, but that the vast majority of the flies that infest dwelling houses both in cities and on farms come from horse manure.

In 1907 careful investigations carried on in the city of Liverpool by Robert Newstead, lecturer in economic entomology and parasitology in the School of Tropical Medicine of the University of Liverpool, indicated that the chief breeding places of the house fly in that city should be classified under the following heads: (1) Middensteads (places where dung is stored) containing horse manure only; (2) middensteads containing spent hops; (3) ash pits containing fermenting materials.

He found that the dung heaps of stables containing horse manure only were the chief breeding places. Where horse and cow manures were mixed, the flies bred less numerously, and in barnyards where fowls were kept and allowed freedom relatively few house flies were found. Only one midden containing warm spent hops was inspected, and this was found to be as badly infested as any of the stable middens. A great deal of time was given to the inspection of ash pits, and it was found that wherever fermentation had taken place and artificial heat had been thus produced such places were infested with house fly larvæ and pupæ often to the same alarming extent as in stable manure. Such ash pits as these almost invariably contained large quantities of old bedding or straw and paper, paper mixed with human excreta, or old rags, manure from rabbit hutches, etc., or a mixture of all these. About 25 per cent of the ash pits examined were thus infested, and house flies were found breeding in smaller numbers in ash pits in which no heat had been engendered by fermentation. The house fly was also found breeding by Mr. Newstead in certain temporary breeding places, such as collections of fermenting vegetable refuse, accumulations of manure at wharves, and in bedding in poultry pens.

Still more recent investigations have been carried on during the year 1908 by Prof. S. A. Forbes, state entomologist of Illinois, who has reared it in large numbers from the contents of paunches of slaughtered cattle, from refuse hog hairs, from tallow vats, from carcasses of various animals, miscellaneous garbage, and so on.

All this means that if we allow the accumulation of filth we will have house flies, and if we do not allow it to accumulate we will have no house flies. With the careful collection of garbage in cans and the removal of the contents at more frequent intervals than ten days, with the proper regulation of abattoirs, and particularly with the proper regulations of stables in which horses are kept, the typhoid fly will become a rare species. It will not be necessary to treat horse manure with chloride of lime or with kerosene or with a solution of paris green or arsenate of lead, if stable men are required to place the manure daily in a proper covered receptacle and it is carried away once a week.

The orders of the health department of the District of Columbia, published May 3, 1906, if carried out, will be very effective. These orders may briefly be condensed as follows:

> All stalls in which animals are kept shall have the surface of the ground covered with a water-tight floor. Every person occupying a building where domestic animals are kept shall maintain, in connection therewith, a bin or pit for the reception of manure, and pending the removal from the premises of the manure from the animal or animals, shall place such manure in said bin or pit. This bin shall be so constructed as to exclude rain water, and shall in all other respects be water-tight except as it may be connected with the public sewer. It shall be provided with a suitable cover and constructed so as to prevent the ingress or egress of flies. No person owning a stable shall keep any manure or permit any manure to be kept in or upon any portion of the premises other than the bin or pit described, nor shall he allow any such bin or pit to be overfilled or needlessly uncovered. Horse manure may be kept tightly rammed into well-covered barrels for the purpose of removal in such barrels. Every person keeping manure in any of the more densely populated parts of the District shall cause all such manure to be removed from the premises at least twice every week between June 1 and October 31, and at least once every week between November 1 and May 31 of the following year. No person shall remove or transport any manure over any public highway in any of the more densely populated parts of the District except in a tight vehicle which, if not inclosed, must be effectually covered with canvas so as to prevent the manure from being dropped. No person shall deposit manure removed from the bins or pits within any of the more densely populated parts of the District without a permit from the health officer. Any person violating any of these provisions shall, upon conviction thereof, be punished by a fine of not more than $40 for each offense.

In addition to this excellent ordinance, others have been issued from the health department of the District of Columbia which provide against the contamination of exposed food by flies and by dust. The ordinances are excellently worded so as to cover all possible cases. They provide for the registration of all stores, markets, cafes, lunch rooms, or of any other place where food or beverage is manufactured or prepared for sale, stored for sale, offered for sale, or sold, in order to facilitate inspection, and still more recent ordinances provide for the registration of stables. An excellent campaign was begun during the summer of 1908 against insanitary lunch rooms and restaurants. A number of cases were prosecuted, but conviction was found to be difficult.

For one reason or another, the chief reason being the lack of a sufficient force of inspectors under the control of the health officer, the ordinance in regard to stables has not been carried out with that perfection which the situation demands. In the summer of 1896 the health officer of the District, Dr. W. C. Woodward, designated a region in Washington bounded by Pennsylvania avenue, Sixth street, Fifteenth street, and the Potomac River, which was to be watched by assistants of the writer. Twenty-four stables were located in this region and were visited weekly by two assistants chosen for the purpose. The result was that on the whole the manure was well looked after and the number of flies in the region in question was very considerably reduced during the time of inspection.

Were simple inspection of stables all that is needed, a force of four inspectors, especially detailed for this work, could cover the District of Columbia, examining once a week all the stables after they had been once located and mapped. The average salary of an inspector is $1,147, so that the total expense for the first year would be about $4,500. But the inspectors' service is complicated by the matter of prosecution. Much of the time of inspectors would be taken in the prosecution of the owners of neglected premises. Moreover, the health officer has found during the summer of 1908 in his prosecution of the owners or managers of insanitary restaurants that his inspectors were practically sworn out of court by the multiplicity of opposing evidence. This means that it will be necessary in such cases to send two inspectors together in all cases, so that the testimony of one may be supported by that of the other. This perhaps would double the number of necessary inspectors, making the expense of the service something over $9,000. It is reasonably safe to state, however, that with such an expense for competent service, or perhaps with a slightly added expense, the typhoid fly could be largely eliminated in the District of Columbia as an element in the transfer of disease; and the difficulty which the authorities have had in locating the cause of a very considerable proportion of the cases of typhoid in the past two or three years indicates plainly to the mind of the writer that the typhoid fly is a much more important element than has been supposed. It is a comforting, although comparatively insignificant, fact that as a matter of common observation in certain sections of the city the typhoid fly has been much less numerous during the past summer than in previous years. The writer is inclined to attribute this to the gradual disappearance of horse stables in such sections, brought about by the rapidly increasing use of motor vehicles.

A significant paragraph in Mr. Newstead's Liverpool report, referred to above, contains the following words:

> The most strenuous efforts should be made to prevent children defecating in the courts and passages; or that the parents should be compelled to remove such matter immediately; and that defecation in stable middens should be strictly forbidden. The danger lies in the overwhelming attraction which such fecal matter has for house flies, which later may afterwards come into direct contact with man or his foodstuffs. They may, as Veeder puts it, "In a very few minutes * * * load themselves with dejections from a typhoid or dysenteric patient, not as yet sick enough to be in hospital or under observation, and carry the poison so taken up into the very midst of the food and water ready for use at the next meal. There is no long, roundabout process involved."

The writer has already referred to this general subject in his remarks on the depositing of excrement in the open within town or city limits, but Newstead's specific reference to children reminds one that in the tenement districts of the older great cities of England and other parts of Europe there occur opportunities for transfer of disease which, while probably less numerous in the newer cities of the United States, nevertheless must still exist and be a constant danger.

We have thus shown that the typhoid or house fly is a general and common carrier of pathogenic bacteria. It may carry typhoid fever, Asiatic cholera, dysentery, cholera morbus, and other intestinal diseases; it may carry the bacilli of tuberculosis and certain eye diseases. It is everywhere present, and may be disposed of with comparative ease. It is the duty of every individual to guard so far as possible against the occurrence of flies upon his premises. It is the duty of every community, through its board of health, to spend money in warfare against this enemy of mankind. This duty is as pronounced as though the community were attacked by bands of ravenous wolves.

As a matter of fact, large sums of money are spent annually in the protection of property in the United States and on matters pertaining to health. But the expenditure for fly protection is very small and misdirected. There is much justification for the criticism published editorally in the Journal of the American Medical Association for August 22, 1908, under the caption "National farm commission and rural sanitation:"

> The President calls attention to the fact that all efforts to aid the farmers have hitherto been directed to improving their material welfare, while the man himself and his family have been neglected. Nowhere is this more marked than in the attitude of the General Government in matters relating to sanitation. It is a trite saying that whereas the Government, through the Department of Agriculture, aids the farmer generously in caring for the health of his hogs, sheep, etc., it does nothing for his own health. The Government issues notices to the farmer of the injury done to his crops by the cotton-boll weevil and the potato bugs and how to combat it, but the injury the mosquito does in spreading malaria to the people who pick the cotton and hoe the potatoes is not impressed on him. The fact that horseflies may carry anthrax to his cattle is dealt with at considerable length, but the diseases which the house fly spreads to the milk and to the farmer's family attract practically no attention. How to build a hog pen or a sanitary barn is the subject of a number of government publications, but how to build a sanitary privy, which will prevent the spread of typhoid, hook-worm, and many other diseases, is regarded as of strictly local interest.

But this criticism is not entirely justified, since there was published by the Bureau of Entomology of the United States Department of

Agriculture in 1900 a Farmers' Bulletin entitled "How Insects Affect Health in Rural Districts," in which all of the points mentioned by the editor of the Journal of the American Medical Association have been touched upon, and at the date of present writing 192,000 copies of this bulletin have been distributed among the people. Moreover, a number of years ago a circular was published on the subject of the house fly, calling attention to its dangers and giving instructions such as are covered in a general way in this article, and some 18,000 copies of this circular have also been distributed. This is an indication that the General Government is by no means blind to the people's needs in such matters as we have under consideration, but further work should be done. That the English Government is awaking to the same need is shown by the fact that in the parliamentary vote of the present year, in aid of scientific investigations concerning disease, one of the projects supported by the General Government was the investigation of Doctors Copeman and Nuttall on flies as carriers of disease.

A leading editorial in the Washington Evening Star of October 20, 1908, bears the heading "Typhoid a national scourge," arguing that it is to-day as great a scourge as tuberculosis. The editorial writer might equally well have used the heading "Typhoid a national reproach," or perhaps even "Typhoid a national crime," since it is an absolutely preventable disease. And as for the typhoid fly, that a creature born in indescribable filth and absolutely swarming with disease germs should practically be invited to multiply unchecked, even in great centers of population, is surely nothing less than criminal.

ENDEMIC DISEASE AS AFFECTING THE PROGRESS OF NATIONS.

In referring to the spread of malaria in Greece, the influence of this disease on the rise and fall of national power has been touched upon in an earlier paragraph of this report. The subject is one of the widest importance and deserves a more extended consideration.

The following paragraphs are quoted from Ronald Ross's address on "Malaria in Greece," delivered before the Oxford Medical Society November 29, 1906:

> Now, what must be the effect of this ubiquitous and everlasting incubus of disease on the people of modern Greece? Remember that the malady is essentially one of infancy among the native population. Infecting the child one or two years after birth, it persecutes him until puberty with a long succession of febrile attacks, accompanied by much splenomegaly and anæmia. Imagine the effect it would produce upon our own children here in Britain. It is true that our children suffer from many complaints—scarlatina, measles, whooping cough—but these are of brief duration and transient. But now add to these, in imagination, a malady which lasts for years, and may sometimes attack every child in a village. What would be the effect upon our population, especially our rural population—upon their numbers and upon the health and vigor of the survivors? It must be enormous in Greece. People often seem to think that such a plague strengthens a race by killing off the weaker individuals; but this view rests upon the unproven assumption that it is really the weaker children which can not survive. On the contrary, experience seems to show that it is the stronger blood which suffers most—the fair, northern blood which nature attempts constantly to pour into the southern lands. If this be true, the effect of malaria will be constantly to resist the invigorating influx which nature has provided; and there are many facts in the history of India, Italy, and Africa which could be brought forward in support of this hypothesis.

> We now come face to face with that profoundly interesting subject, the political, economical, and historical significance of this great disease. We know that malaria must have existed in Greece ever since the time of Hippocrates, about 400 B. C. What effect has it had on the life of the country? In prehistoric times Greece was certainly peopled by successive waves of Aryan invaders from the North, probably a fair-haired people, who made it what it became, who conquered Persia and Egypt, and who created the sciences, arts, and philosophies which we are only developing further to-day. That race reached its climax of development at the time of Pericles. Those great and beautiful valleys were thickly peopled by a civilization which in some ways has not since been excelled. Everywhere there were cities, temples, oracles, arts, philosophies, and a population vigorous and well trained in arms. Lake Kopais, now almost deserted, was surrounded by towns whose massive works remain to this day. Suddenly, however, a blight fell over all. Was it due to internecine conflict or to foreign conquest? Scarcely; for history shows that war burns and ravages, but does not annihilate. Thebes was thrice destroyed, but thrice rebuilt. Or was it due to some cause, entering furtively and gradually, sapping away the energies of the race by attacking the rural population, by slaying the new-born infant, by seizing the rising generation, and especially by killing out the fair-haired descendant of the original settlers, leaving behind chiefly the more immunized and darker children of their captives, won by the sword from Asia and Africa? * * *
>
> I can not imagine Lake Kopais, in its present highly malarious condition, to have been thickly peopled by a vigorous race; nor, on looking at those wonderful figured tombstones at Athens, can I imagine that the healthy and powerful people represented upon them could have ever passed through the anæmic and splenomegalous infancy (to coin a word) caused by widespread malaria. Well, I venture only to suggest the hypothesis, and must leave it to scholars for confirmation or rejection. Of one thing I am confident, that causes such as malaria, dysentery, and intestinal entozoa must have modified history to a much greater extent than we conceive. Our historians and economists do not seem even to have considered the matter. It is true that they speak of epidemic diseases, but the endemic diseases are really those of the greatest importance. * * *
>
> The whole life of Greece must suffer from this weight, which crushes its rural energies. Where the children suffer so much, how can the country create that fresh blood which keeps a nation young? But for a hamlet here and there, those famous valleys are deserted. I saw from a spur of Helicon the sun setting upon Parnassus, Apollo sinking, as he was wont to do, toward his own fane at Delphi, and pouring a flood of light over the great Kopaik plain. But it seemed that he was the only inhabitant of it. There was nothing there. "Who," said a rich Greek to me, "would think of going to live in such a place as that?" I doubt much whether it is the Turk who has done all this. I think it is very largely the malaria.

In considering carefully this suggestive argument of Major Ross, does it not appear to indicate the tremendous influence that the prevalence of endemic disease must exert upon the progress of modern nations, and does it not bring the thought that those nations that are most advanced in sanitary science and preventive medicine will, other things being equal, assume the lead in the world's work? Who can estimate the influence of the sanitary laws of the Hebrew scriptures upon the extraordinary persistence of that race through centuries of European oppression, centuries full of plague years and of terrible mortality from preventable disease? And what more striking example can be advanced of the effect of an enlightened and scientifically careful attention to the most recent advances of preventive medicine upon the progress of nations than the mortality statistics of the Japanese armies in the recent Russian-Japanese war as compared with the corresponding statistics for the British army during the Boer war immediately preceding, or the American army during the Spanish war at a somewhat earlier date?

The consideration of these elements of national progress has been neglected by historians, but they are nevertheless of deep-reaching importance and must attract the immediate attention in this age of advanced civilization. The world has entered the historical age when national greatness and national decay will be based on physical rather than moral conditions, and it is vitally incumbent upon nations to use every possible effort and every possible means to check physical deterioration.

SUMMARY OF LOSSES FROM INJURIOUS INSECTS.

This report on the economic loss to the people of the United States through insects that carry disease is one of a series of reports made to the Commission on the Conservation of Natural Resources on the losses due to injurious insects. The insect losses in the United States are undoubtedly heavier than in any other country in the world. There are many insect pests for every plant grown on the farm and for every kind of tree represented in our natural forests. All domestic animals suffer seriously from parasitic and other insects, and above the reduction in the annual increase of products is the heavy loss occasioned by insects to the accumulated stores of previous years of such staples as grains, tobacco, manufactured woods, hides and furs, and certain animal food products. There is in addition, also, the serious check on production caused by the prevalence of insect-borne diseases.

Estimating all of these losses at the lowest reasonable percentage, a total so enormous is reached that it staggers the belief of anyone who has not given the subject careful study or considered the enormous annual output of products involved.

To meet the requirements of the schedule of inquiries submitted, the losses which are chargeable to insect pests fall under four heads, namely, (1) relating directly to plant products other than natural forests; (2) relating to natural forests and forest products; (3) due to insect enemies of live stock; and (4) due to the relation of insects to disease. To get a comprehensive view, the amount of loss estimated as falling under each of these four heads is here indicated.

Subject.	Percentage of loss on annual output or value.	Amount of loss.
Plant products of the farm	10-30	$652,500,000
Natural forest products	10	130,000,000
Animal products	10	267,000,000
Insects versus disease		200,000,000
Total		1,249,500,000
